Because of the relative difficulty of performing routine estrogen and progesterone receptor assays on CMTs, the use of hormonal therapy in dogs with mammary tumors has lagged behind that in human oncology. In addition to the efforts at hormone ablation via ovariectomy described previously, tamoxifen is a drug that has been evaluated as hormonal therapy for CMTs. Tamoxifen has both estrogenic and antiestrogenic effects and has been advocated for many years for the treatment of estrogen receptor-positive human breast cancer patients. A pilot study evaluated outcome for 16 dogs with mammary carcinoma treated with 2.5 to 10mg (mean dose 0.42mg/kg q12h PO) of tamoxifen. Five of seven dogs with either metastatic or nonresectable mammary carcinoma experienced a decrease in tumor burden. In another report of 10 dogs with advanced mammary cancer treated with 0.7mg/kg of tamoxifen every 24 hours, no measurable responses were noted. Adverse effects, including vaginal discharge, vulvar swelling, urinary incontinence, urinary tract infection,

mental dullness, signs of estrus, and partial alopecia have been seen in dogs undergoing tamoxifen therapy. One quarter of the treated dogs in the former study developed pyometra (one closed-cervix pyometra and three stump pyometras). An identical rate of pyometra (20%) induction was also seen in a 1988 report of 20 bitches treated with 1 mg/kg of tamoxifen every 12 hours orally for 10 days for prevention or termination of pregnancy. Thus clients must be counseled regarding this potential side effect if tamoxifen therapy is to be considered.

Various nonspecific immunomodulatory approaches have been investigated for the treatment of CMTs, including *Corynebacterium parvum*, bacillus Calmette-Guérin (BCG), levamisole, and liposome-encapsulated muramyl tripeptide phosphatidylethanolamine. However, none have been clearly demonstrated to be of clinical benefit for dogs with CMT.

Therapy for Inflammatory Mammary Carcinoma

Although no therapy option has been shown to be of significant benefit for dogs with IMC, there is general agreement among veterinary oncologists that surgery is contraindicated. Wound dehiscence, ventral and limb edema, and disseminated intravascular coagulation are

all potential complications of IMC, which is unlikely to be amenable to complete surgical excision. There are anecdotal reports of disease palliation with radiation therapy, nonsteroidal antiinflammatory drugs, and doxorubicin-based chemotherapy protocols, but the prognosis remains poor despite all treatment attempts reported to date.

Prognosis

Prognostic factors for CMTs have been examined in multiple prospective and retrospective studies. Factors determined to correlate with prognosis in multivariate analysis are the most compelling since the interdependent effects of multiple factors are considered in such analyses. Although conflicting reports exist regarding the impact of many factors on prognosis, those generally accepted to have a negative impact on prognosis are listed in Table 79-4.

FELINE MAMMARY CANCER

Incidence, Etiology, and Pathogenesis

Mammary cancer is the third most common feline tumor after skin tumors and lymphoma. As in dogs, mammary

Table 79-4		
Comparative Aspect of Canine and Feline Mammary Tumors		
	Dog	Cat
Estimated annual incidence in the United States	199/100,000	25/100,000
Percent of tumors that are benign	50-70	10-20
Most common malignancy	Complex carcinoma	Tubulopapillary carcinoma
Hormone receptor expression in invasive carcinomas	Majority (62.5%) are ER-α+ and PR-	Majority (57%) are ER-α- and PR+
Genetic mutations	BRCA1 and BRCA2 Unknown HER-2/neu Protein overexpressed in 17.6% p53 15%-75%	Unknown Protein overexpressed in 59.6% 19%-33%
Metastatic behavior	32%-77%, depending on histologic type	>50% Metastatic
Poor prognostic factors	Diagnosis of ductal carcinoma, Inflammatory mammary carcinoma or sarcoma Ulceration of skin Invasive growth; fixed to adjacent tissue Increased age at diagnosis Estrogen receptor negative German shepherd breed Heat shock protein expression Advanced stage Large tumor size >3 cm High histologic grade Nodal or pulmonary metastasis Nonovariectomized	High AgNOR count Tumor size >3 cm Ki-67 index >25.2 Lymphatic invasion Increased WHO stage
Overall prognosis	Reported mean survival time (MST): 439 days MST: 70 weeks after surgery for malignant vs. 114 weeks for benign tumors	1-year survival noted for ≈1/3 to 1/2 of cats treated with surgery alone; up to 59% with adjuvant chemotherapy 2-year survival is ≈15%-20% with surgery alone; improves to ≈37% with addition of chemotherapy

tumors may affect both male and female cats. Both estrogen and progesterone are thought to play important roles in feline mammary cancer (FMC) development, although the underlying mechanisms are less clear than for CMTs. Intact females and cats exposed regularly to progestins have been shown to be at an increased risk for mammary cancer development. The literature also suggests that, as in dogs, early ovariectomy may lower the risk of developing FMC. One published report demonstrated that cats ovariectomized at 6 months of age had an approximately sevenfold reduction in risk of FMC compared to intact cats (Dorn et al., 1968). A more recent study compared a population of 308 cats with biopsy-proven FMC to a control population of 400 female cats that were not diagnosed with mammary tumors (Overley et al., 2005). There was a statistically significant reduction in risk of FMC development reported for cats spayed before 1 year of age compared to intact cats. Specifically a 91% reduction in risk was reported for those spayed before 6 months of age, and an 86% reduction was demonstrated in those spayed before 1 year of age. Parity was not significantly related to risk of developing FMC. Thus there is some justification for recommending ovariohysterectomy before 1 year of age in cats.

Clinical Presentation

As is the case in dogs, the presentation associated with FMC generally relates to a palpable nodule detected by the owner or veterinarian. However, in contrast to dogs the majority (80% to 96%) of mammary tumors in cats are malignant. Ulceration of lesions is not uncommon and is suggestive of malignancy. As in the dog, multiple lesions are often present at the time of diagnosis, although cats are less likely to have a combination of benign and malignant lesions.

Diagnostics and Staging

Complete evaluation of a cat with suspected mammary carcinoma should include an assessment of general health with a urinalysis, complete blood count, and serum

biochemical evaluation in anticipation of anesthesia and surgery. Thoracic radiographs (right lateral, left lateral, and ventrodorsal views) and regional lymph node palpation/aspiration are critical, given that the reported metastatic rate for FMC ranges from 25% to as high as 100%, with the most common sites being the lymph nodes and lungs. In a review of the literature between 1952 and 1996, Waters and associates (1998) found 338 cases of extraskelatal metastases in 799 cats with malignant mammary tumors. Interestingly, cats have a very low rate of skeletal metastasis from mammary carcinoma compared to people and dogs.

Histopathologic examination is necessary to confirm a diagnosis of FMC. Often biopsy specimens are obtained at the time of definitive surgery rather than as a presurgical evaluation. The majority of mammary tumors in cats are diagnosed as adenocarcinomas, specifically of tubular, papillary, solid, or cribriform type. Less common malignant lesions include squamous cell carcinomas, sarcomas, and mucinous carcinomas. IMC was first described in cats in 2004, with three cats having lesions typical in gross appearance to that of human and canine IMC and with a similar poor prognosis. Features in the feline IMC that differed from those typical of human or canine IMC included positive immunohistochemical staining for ER- α , occurrence only after prior mastectomy, and severe inflammation of the dermis and subcutaneous tissue.

As described for dogs, fine-needle aspiration and cytology of mammary lesions is seldom of clinical use but may be considered if cutaneous or subcutaneous lesions of nonmammary tissue origin such as mast cell tumors are suspected. Cytologic evaluation of pleural effusion fluid or of aspirates from enlarged lymph nodes is warranted when these conditions are present. As with dogs, the staging system for FMC has been modified from the original system proposed by Owen in 1980. The modified system limits nodal metastasis to stage III or IV, whereas the original system placed those with histologically confirmed nodal metastasis but without fixation of nodes to surrounding tissue into stage II. A comparison of the staging systems is outlined in Table 79-5.

Table 79-5

Comparison of the Original and Modified Staging Systems for the Classification of Feline Mammary Carcinoma

Stage	Original WHO Staging	Modified WHO Tumor Staging
I	T1 (<1 cm) N ₀ M ₀	T ₁ (<2 cm) N ₀ M ₀
II	≤T2 (<3 cm) N ₁₊ M ₀ (histologically positive node, but not fixed to underlying tissues)	T ₂ (2 to 3 cm) N ₀ M ₀
III	Any T3 or any with fixed nodal involvement	Regional node metastasis or T3 (>3 cm) lesion or both, but no distant metastasis
IV	Distant metastasis (any T, any N, M ₁)	Distant metastasis (any T, any N, M ₁)

TNM system: T, size of primary tumor; N, regional lymph node involvement; M, distant metastasis. For example, N₀ is without lymph node involvement, and N₁ is confirmed lymph node involvement. WHO, World Health Organization.

Treatment

Surgery

Surgery is the primary treatment for FMC, often with adjuvant chemotherapy. Unlike the recommendations for CMT, unilateral or bilateral mastectomy is generally considered the preferred surgical method in cats. There are conflicting reports regarding whether radical mastectomy provides a survival advantage, although the procedure has been shown to significantly decrease the recurrence rate of FMC. When bilateral radical mastectomy is performed, it may be done as one surgical procedure or as a staged procedure, with the second unilateral mastectomy 2 to 6 weeks after the first. The inguinal lymph node is removed with the caudal mammary glands; however, axillary node excision is not a routine part of the radical mastectomy. Removal of the axillary node is only recommended if it is known to have metastatic disease since prophylactic axillary node excision is unlikely to benefit the patient.

Chemotherapy

Few studies have assessed the role of chemotherapy for the primary or adjuvant treatment of FMC. Doxorubicin-based protocols have been evaluated most frequently, with approximately one third to one half of cats with stage III or IV disease (see Table 79-5 for staging criteria) having measurable responses to the combination of doxorubicin and cyclophosphamide. In a recent retrospective study of 67 cats with mammary adenocarcinoma receiving adjuvant doxorubicin chemotherapy (1 mg/kg q21d IV for an intended five treatments) beginning at the time of suture removal, the median survival time was 448 days, and the 1- and 2-year survival rates were 58.9% and 37.2%, respectively (Novosad et al., 2006). I and others have recently completed a randomized, prospective clinical trial comparing mitoxantrone (5 mg/m² q21d IV for four total doses) to doxorubicin (four doses at 20 mg/m² q21d IV) for adjuvant therapy of FMC after radical mastectomy. Data analysis indicates no significant difference in survival times between the two groups, with median survival times of 747 days for the mitoxantrone group and 484 days for the doxorubicin group. The literature supports use of adjuvant chemotherapy for advanced-stage FMC, although its role for treatment of Stage I tumors is less clear.

Prognosis

Size of a mammary tumor and therefore T stage according to the WHO staging system is the single most reliable prognostic indicator in cats. In one report the median survival time for cats with tumors larger than 3 cm was 12 months compared to 21 months for cats with lesions less than 3 cm. Other prognostic factors and a summary of the literature regarding survival times are shown in Table 79-4.

Urinary Bladder Cancer

DEBORAH W. KNAPP, *West Lafayette, Indiana*

CANINE URINARY BLADDER TUMORS

Urinary bladder cancer comprises approximately 2% of all reported malignancies in the dog. With the pet dog population in the United States exceeding 65 million, this translates into several thousand cases of urinary bladder cancer annually. The hospital prevalence or proportionate morbidity of bladder cancer at university-based veterinary hospitals is also increasing (Knapp et al., 2000a; Mutsaers, Widmer, and Knapp, 2003).

Transitional cell carcinoma (TCC) is the most common form of canine urinary bladder cancer (Knapp et al., 2000a; Mutsaers et al., 2003; Valli et al., 1995). The majority of dogs that develop TCC have papillary infiltrative cancer of intermediate- to high-grade TCC, with only a small percentage of dogs having low-grade, superficial TCC (Norris et al., 1992; Valli et al., 1995). TCC is most often located in the trigone region of the bladder. Papillary lesions and bladder wall thickening can lead to partial or complete urinary tract obstruction. In a series of 102 dogs with TCC, the tumor involved the urethra (as well as the bladder) in 57 of 102 dogs (56%) and the prostate in 11 of 38 (29%) male dogs (Knapp et al., 2000a). In addition to causing urinary tract problems, TCC has the propensity to metastasize to other organs. The most common sites of TCC metastases are regional lymph nodes and lung. Less common sites of metastases include liver, kidney, spleen, prescapular lymph node, heart, uterus, cecum, bone, ilium, colon, abdominal wall, diaphragm, eye, and oral mucosa.

The clinician should not assume that all bladder masses are TCC. Mass effects in the bladder can occur with benign conditions, such as polyps and inflammatory lesions, or with other tumors. The latter can include squamous cell carcinoma, adenocarcinoma, undifferentiated carcinoma, lymphoma, rhabdomyosarcoma, hemangiosarcoma, fibroma, and other mesenchymal tumors (Norris et al., 1992; Valli et al., 1995).

Etiology and Possible Prevention Strategies

The etiology of canine bladder cancer is not completely known but is most likely multifactorial. Risk factors identified include exposure to older-generation flea control products (dips, powders, sprays), herbicides, and insecticides; obesity; possibly cyclophosphamide administration; female gender (female:male ratio 1.7:1); and breed (Glickman et al., 2004; Knapp et al., 2000a; Mutsaers et al., 2003; Raghavan et al., 2004). Breeds at increased risk of TCC are listed in Table 80-1.

It is appropriate to educate dog owners of high-risk breeds regarding the predisposition for TCC in their pets, especially with advancing age. Pet owners should be aware of notable clinical signs of disease (hematuria, stranguria, inappropriate urination). Some form of disease screening can be considered in older at-risk dogs (such as urinalysis with sediment examination, urine antigen test, abdominal ultrasound, more frequent physical examination), although the most effective and appropriate methods of TCC screening approaches have not been determined.

The development of TCC is thought to represent a combination of genetic factors and environmental exposures. An association between herbicide exposure and TCC in dogs was identified in a case control study in 166 Scottish terrier dogs (Glickman et al., 2004). Exposure to herbicides was compared between TCC cases ($n = 83$) and control dogs ($n = 83$; Scottish terriers at least 6 years of age with no evidence of TCC and no history of urinary tract disease in the 2 years before entry into the study). TCC risk was significantly increased in dogs exposed to lawns or gardens treated with herbicides alone or gardens treated with herbicides and insecticides, although not with insecticides alone. It is likely that important gene-environment interactions were involved in the TCC development. Results of this study indicate the importance of limiting dogs' exposure to herbicides, especially in breeds of dogs at increased risk for TCC.

An earlier case-control study revealed an association between TCC and exposure to topical application of flea and tick dips (summarized in Knapp et al., 2000). In the highest-risk group (overweight female dogs), the risk for TCC was 28 times that of normal-weight male dogs not exposed to the insecticides. The authors speculated that the "inert" ingredients (solvents and petroleum distillates), which accounted for more than 95% of the product, were the probable carcinogens. Newer, spot-on types of flea control products appear safer. In a recent case control study in Scottish terriers, spot-on products containing fipronil were not associated with increased risk for TCC (Raghavan et al., 2004).

Recently ingestion of vegetables has been reported to be associated with a lower risk of TCC (Raghavan et al., 2005). In a case control study, Scottish terriers that consumed vegetables at least three times per week along with their normal diet had reduced risk for TCC.

Presentation, Diagnosis, and Clinical Staging

Typically canine TCC is a disease of older dogs. The reported mean age at diagnosis is 11 years. The mean body weight in a series of 102 dogs with TCC was 15.67

Table 80-1

Breed and Risk of Urinary Bladder Cancer in Pet Dogs (Summary Data From Veterinary Medical Data Base)*

Breed	Odds Ratio	95% Confidence Interval
Mixed breed	1.0 [†]	
All pure breeds	0.74	0.62-0.88
Scottish terrier	19.89	7.74-55.72
West Highland white terrier	5.31	2.51-11.63
Shetland sheepdog	4.46	2.48-8.03
Beagle	4.15	2.14-8.05
Wirehaired terrier	3.20	1.19-8.63
Miniature poodle	0.86	0.55-1.35
Miniature schnauzer	0.92	0.54-1.57
Doberman pinscher	0.51	0.30-0.87
Labrador retriever	0.46	0.30-0.69
Golden retriever	0.46	0.30-0.69
German shepherd	0.40	0.26-0.63

* Initially reported in 2000 (Knapp et al., 2000a) with updated information (Knapp and Glickman, unpublished data) added in 2006.

[†]Reference category.

± 10.25 kg (range 3 to 51 kg), and the female-to-male ratio was 1.7:1 (Knapp et al., 2000a). Common clinical signs in dogs with TCC include hematuria, dysuria, pollakiuria (often of chronic or recurrent nature), and less commonly lameness caused by bone metastasis or hypertrophic osteopathy. It is important to note that the lower urinary tract signs observed with TCC are not distinguishable from those that occur with urinary tract infection or calculi. Factors that raise suspicion for TCC include persistent or recurrent lower urinary tract signs or infection (especially after appropriate dose and duration of antibiotic therapy based on culture and sensitivity), older age, and high-risk breed.

The physical examination of a dog with possible TCC should include a thorough rectal examination. The extent of findings may depend somewhat on the size of the dog, but findings could include thickening of the urethra, prostatic enlargement, a trigonal mass, and/or enlarged lymph nodes. Abdominal palpation may reveal a distended bladder. Bladder masses often are not detected on abdominal palpation, and normal physical examination does not rule out TCC.

When TCC is suspected, the clinician should pursue tests to (1) make a definitive diagnosis, (2) determine the stage of the cancer if present, and (3) assess the overall health of the patient. This evaluation could include complete blood count, serum biochemistry profile, urinalysis, urine culture, thoracic radiography, abdominal ultrasonography, and bladder imaging (contrast cystography or cystosonography). Urine should be obtained by free catch or catheter sample and not by cystocentesis, which may seed the TCC along the needle track.

A diagnosis of TCC requires histopathologic confirmation. Although neoplastic cells may be present in the urine of 30% of dogs with TCC, cancer cells are often

indistinguishable from reactive epithelial cells associated with inflammation. Urine antigen tests for TCC have been found to be sensitive for TCC, but high numbers of false-positive results limit the value of these tests. It is essential to perform histopathologic examination of the abnormal tissues to determine if TCC is present. Methods for obtaining tissue for histopathologic diagnosis include cystotomy, cystoscopy, and traumatic catheterization. If surgery is performed, *great care must be taken to avoid TCC seeding*. Similarly percutaneous biopsy methods (e.g., transabdominal ultrasound-guided needle core biopsies or fine-needle aspirates) should be avoided because these can lead to tumor seeding.

Thoracic radiography and abdominal ultrasonography are recommended to evaluate for metastases. Lymph node and distant metastases were present in 16% and 14% of 102 dogs, respectively, at the time of diagnosis of TCC in one study (Knapp et al., 2000a). Distant metastases were detected in 50% of dogs at the time of death. Tumor stage can be assigned following the World Health Organization clinical staging system for canine bladder tumors (Box 80-1). In addition to detecting enlarged lymph nodes or other organ metastases, abdominal ultrasound is useful for detecting ureteral obstruction and hydronephrosis. This could be an indication for the placement of ureteral stent(s), especially if other therapies do not relieve the urinary obstruction (see Chapter 209).

Bladder imaging is recommended to determine the location of the tumor within the urinary tract and to obtain baseline measurements to monitor response to subsequent therapy. Cystography has been the traditional method of bladder imaging. It is best performed with the patient anesthetized, with air (4 to 9 ml/kg, depending on bladder capacity) and positive contrast (0.1 to 0.2 ml/kg) instilled in the bladder and with images made in right lateral, left lateral, and ventrodorsal recumbency. Caution must be taken when passing a urinary catheter during

Box 80-1

World Health Organization Clinical Stage (TNM) of Canine Urinary Bladder Cancer

T: Primary tumor

Tis: Carcinoma in situ

- T0 No evidence of primary tumor
- T1 Superficial papillary tumor
- T2 Tumor invading the bladder wall, with induration
- T3 Tumor invading neighboring organs (prostate, uterus, vagina, and pelvic canal)

N: Regional lymph node (internal and external iliac lymph node)

- N0 No regional lymph node involved
- N1 Regional lymph node involved
- N2 Regional lymph node and juxta regional lymph node involved

M: Distant metastases

- M0 No evidence of metastasis
- M1 Distant metastasis present

TNM, Tumor, node, metastasis.

diagnostic procedures to avoid penetration of the diseased bladder or urethral wall.

Ultrasonography has also been used to image the bladder. As with cystography, the degree of bladder distention is important when performing ultrasonography. When the bladder is empty or minimally distended, it may be difficult to visualize some lesions, and it is not possible to determine if evident lesions are invading or remote to the trigone (where surgical resection may be possible). When using ultrasonography to monitor tumor size during therapy, consistent bladder distention (on repeated visits) is important. Some bladder masses appear smaller in a well-distended bladder than in a less-distended bladder. When multiple lesions are present, lesions can become superimposed within the less-distended bladder, making comparison of tumor burden between studies difficult. For the most accurate comparison of bladder mass size between visits, a urinary catheter should be passed, and the bladder distended with the same volume of sterile saline for each examination. The amount of saline needed to distend the bladder varies from case to case, depending on bladder capacity (which could be lessened by tumor or previous surgery) but is typically 4 to 9 ml/kg. Measuring the bladder masses in at least two consistent planes (e.g., dorsal, transverse) and having the same examiner each time fosters a more accurate assessment of mass volume change over time.

Urinary cystoscopy, using either rigid or flexible cystoscopes, provides a means of visualizing the mucosal surface of the urinary bladder and urethra. The tumor location and involvement of the ureteral stomas may be determined by this imaging. Often, urethral involvement of bladder tumors that is not readily appreciated using ultrasound or contrast studies can be identified with cystoscopy. Most small endoscopes used for cystoscopy have ports that allow the operator to biopsy tumor tissue.

TCC can infrequently metastasize to bone. Radiographs or bone scan may be considered if lameness is present that is not easily explained by other orthopedic or neurologic disease.

Treatment

Surgery

Surgical excision of TCC should be considered for lesions in the bladder apex in which 3-cm margins of grossly normal bladder can be removed around the tumor mass. Unfortunately most TCCs are trigonal and many involve the urethra, precluding surgical excision. In addition, many dogs appear to develop multifocal TCC in the bladder. This is consistent with the "field effect" proposed in human bladder cancer patients, in which the entire bladder lining is thought to undergo malignant change in response to exposure to carcinogens in urine. In a series of 67 dogs with TCC that underwent surgery for biopsy or for therapeutic intent at Purdue University, complete surgical excision of the tumor with tumor-free margins was only possible in two dogs. One of these two dogs had relapse in the bladder 8 months later, and the second dog developed metastatic disease. Transurethral resection of bladder and urethral tumors has been attempted in a small number of dogs but has been limited by complications of

the procedure and local disease recurrence. Carbon dioxide laser ablation of bladder tumor tissue combined with medical therapy also has been reported, but it is not currently known if this approach offers an advantage over traditional surgery and medical therapy.

Surgery has also been used as an emergency palliative procedure to debulk nonresectable tumors in dogs with urinary tract obstruction. Other procedures to bypass urinary obstruction such as the placement of ureteral and urethral stents (Chapter 209) and prepubic cystostomy tubes (see Section IV on Evolve) have also been used.

Radiation Therapy

Studies of the effects of radiation therapy on TCC are very limited. Whole-bladder intraoperative radiation therapy was evaluated in 11 dogs with TCC and 2 dogs with other bladder tumors several years ago (Walker, 1987). Although 1- and 2-year survival rates were encouraging at 69% and 23%, respectively, complications of therapy (urinary incontinence and cystitis with accompanying pollakiuria and stranguria) detracted from quality of life. Other studies have confirmed the complications associated with pelvic radiation.

Medical Therapy of TCC

Medical management of TCC is indicated in dogs with nonresectable or metastatic tumors. Medical therapy of TCC has consisted of chemotherapy, cyclooxygenase (COX) inhibitors (also referred to as nonsteroidal antiinflammatory drugs), and combinations of these two types of treatment (Henry et al., 2003; Knapp et al., 2000a; Knapp et al., 2000b; Mutsaers et al., 2003). Study results support at least three options for the medical therapy of dogs with TCC: (1) COX inhibitor alone, (2) mitoxantrone combined with a COX inhibitor, or (3) referral for participation in clinical trials of other therapy.

COX inhibitor treatment. The non-selective COX inhibitor that has been used the most in dogs with TCC is piroxicam. Piroxicam as a single agent provides a useful palliative treatment for dogs with TCC (Knapp et al., 2000a; Mutsaers et al., 2003). The quality of life in most dogs receiving piroxicam is excellent. Tumor responses in 62 dogs with TCC receiving piroxicam as a single agent included 2 complete responses (CRs), 9 partial responses (PRs, 50% or greater reduction in tumor volume), 35 stable disease (SD, <50% change in tumor volume), and 16 progressive disease (PD). The two dogs that had CR died of nontumor-related causes more than 2 years after beginning piroxicam therapy and were free of tumor on postmortem examination. The survival time in piroxicam-treated dogs (median 195 days) compares favorably to that of 55 dogs in the Purdue Comparative Oncology Program Tumor Registry treated with debulking surgery alone (median survival 109 days). Piroxicam has been used at a dosage of 0.3 mg/kg orally every 24 hours in dogs. It is necessary to have a compounding pharmacy prepare piroxicam for use in small to medium-sized dogs because the commercially available 10-mg capsules are too large for dogs of this size.

Although the majority of dogs tolerate piroxicam well, care must be taken to detect any *gastrointestinal toxicity*

that may occur. If vomiting, melena, or anorexia occurs, it is important to withdraw piroxicam and give supportive care as needed until the toxicity resolves. If piroxicam is to be reinstituted, misoprostol may be given along with the piroxicam to reduce the risk of gastrointestinal irritation.

It is not currently known if selective COX-2 inhibitors have the same antitumor activity as nonselective COX inhibitors. Because COX-2 is overexpressed in the majority of canine TCC and COX-2 is considered a major target of COX inhibitor therapy, selective COX-2 inhibitors may have similar antitumor activity. Selective COX-2 inhibitors have an advantage of causing fewer gastrointestinal side effects than nonselective COX inhibitors.

Chemotherapy combined with COX inhibitor. The results of single-agent chemotherapy for TCC have been disappointing, with remission rates typically less than 20%. However, studies of cisplatin combined with piroxicam have demonstrated an additive to synergistic effect (Knapp et al., 2000b). Although the antitumor activity of cisplatin combined with piroxicam has been impressive (50% to 70% remission rate), renal toxicity has been frequent, and this combination of drugs is not recommended. Other attempts to combine platinum chemotherapy and piroxicam have been less rewarding. Reducing the dose of cisplatin did not prevent renal toxicity of cisplatin/piroxicam. Carboplatin/piroxicam induced remission in 38% of dogs, but the duration of remission and survival times were relatively short. Encouraging results have been published when another chemotherapeutic agent, mitoxantrone, was combined with piroxicam. Mitoxantrone (5 mg/m² intravenously q21d) combined with piroxicam induced remission in 35% of dogs with TCC with minimal toxicity, and resulted in a median survival time of 291 days (Henry et al., 2003). Specific information regarding the various chemotherapy agents discussed is provided in Chapters 65 and 66.

Regardless of the treatment regimen pursued, basic concepts apply in tailoring the therapy to the individual dog with TCC. Complete staging of the TCC defining the extent of the disease and size of lesions should be performed before and after approximately 6 weeks of treatment. After the 6 weeks of treatment, if the tumor is smaller or is stable in size and if the treatment is acceptable in regard to any adverse effects, the same treatment should be continued. Restaging should be performed at 6-week intervals, and therapy adjusted as appropriate. If a CR occurs, then treatment should be continued for an additional 6 weeks to address residual microscopic disease. Therapy would also be continued if PR or SD was noted. A particular treatment should be discontinued if PD ($\geq 50\%$ increase in tumor volume or development of new tumor lesions) or unacceptable toxicity is noted. A different therapy could then be considered.

Other therapies for TCC. Although substantial progress has been made in the treatment of canine TCC, much room for improvement exists. Clinical trials of new approaches are important to define better treatment approaches for this deadly disease. By participating in a clinical trial, the pet dog with TCC may gain access to a therapy that will be better than current "standard" medical therapies for TCC, and information gained from that

canine patient will be useful in developing better therapy approaches for other dogs and potentially for humans. Websites posted by veterinary schools, the Veterinary Cancer Society, and veterinary oncologists can provide information to help veterinarians and pet owners learn about TCC trials being performed. See Chapter 63 for additional information about clinical trials.

In addition to new drugs under study, different types of therapy approaches are also being studied. Photodynamic therapy (PDT) is under study as a treatment for TCC. Following promising *in vitro* studies and studies in normal dogs, PDT with 5-aminolevulinic acid was given to five dogs with TCC, resulting in tumor progression-free intervals ranging from 4 to 34 weeks (median 6 weeks). Because of the possibility of posttreatment swelling of diseased tissues (possibly leading to reduced urine flow), dogs with TCC must be selected carefully for PDT.

Supportive care. Dogs with TCC are at high risk for secondary bacterial infections. Urinalysis and urine culture should be performed regularly, and antibiotics prescribed as needed. Antibiotic therapy should be based on results of urine culture and sensitivity testing, and the appropriate antibiotic should be given for 3 weeks or more. Urination should be monitored closely. If urinary tract obstruction occurs, catheterization, definitive anticancer therapy, antibiotics to reduce inflammation associated with secondary bacterial infection, surgical debulking, or placement of stents or a cystostomy tube to relieve obstruction could be considered.

Prognosis

Unfortunately most dogs that develop TCC ultimately die or are euthanized related to the disease. However, it is possible for many dogs with TCC to live several months or longer with a good quality of life, especially with favorable response to therapy. Median survival times in several studies have exceeded 6 months. Even with piroxicam treatment alone, approximately 20% of dogs survive more than 1 year. Survival has been strongly associated with tumor, node, metastasis (TNM) stage at diagnosis. Using data from 102 dogs with TCC at Purdue University, factors associated with more advanced TNM stage at diagnosis included younger age (increased risk of nodal metastasis), prostate involvement (increased risk of distant metastasis), and higher T stage (increased risk for nodal and distant metastasis) (Knapp et al., 2000). More advanced T stage at diagnosis and glandular differentiation in histopathologic examination were associated with poor response to medical therapy. Recently urethral involvement has also been associated with greater probability of the development of metastatic disease.

FELINE URINARY BLADDER TUMORS

Information concerning urinary bladder cancer in cats is very limited. A report of a series of 27 feline bladder tumors included 15 carcinomas, 5 benign mesenchymal tumors, 5 malignant mesenchymal tumors, and 2 cats with lymphoma (Schwarz, Greene, and Patnaik, 1985). There were 20 male and 7 female cats, and most were elderly. The treatment of feline bladder tumors has not been defined. Results

of partial cystectomy were reported in nine cats, and four cats (two with leiomyoma, one with hemangiosarcoma, and one with leiomyosarcoma) survived longer than 6 months.

CHAPTER 81

Mast Cell Tumor

CHERYL A. LONDON, *Columbus, Ohio*

BIOLOGY AND FUNCTION OF MAST CELLS

Mast cells are derived from the bone marrow and migrate to tissues throughout the body where they undergo differentiation. They are discrete round cells possessing distinct cytoplasmic granules that stain with dyes such as toluidine blue, Giemsa, and methylene blue. These granules may not be visualized with stains such as Diff-Quik, precluding identification on some cytologic specimens. Mature mast cells bind immunoglobulin (Ig)E on their cell surface through expression of the high-affinity IgE receptor. Cross-linking of IgE results in the release and production of various mediators, including histamine; heparin; proteases; lipid mediators; and cytokines such as TNF- α , interleukin (IL)-4, IL-5, and IL-6. These mediators induce increased vascular permeability, vasodilation, smooth muscle spasm, pruritus, and anticoagulation and activate eosinophils and neutrophils. Collectively these effects can lead to local hypersensitivity reactions, or more seriously, systemic hypersensitivity (anaphylactic shock). As such, mast cells have primarily been associated with allergic reactions/disorders. However, it is now evident that they play an important role in the initiation of innate immune responses, particularly with respect to sustaining neutrophil migration and activa-

tion in response to bacteria (Galli, Maurer, and Lantz, 1999). Indeed, mast cells are often seen at sites of inflammation, as well as in reactive lymph nodes. Therefore, in addition to playing a role in the induction of pathologic allergic responses, mast cells are critical players in protective immune responses.

Kit is a tyrosine kinase receptor found on mast cells (as well as hematopoietic stem cells and melanocytes, among others), and its ligand, stem cell factor (SCF), is produced by stromal cells. Binding of Kit by SCF induces downstream signal transduction that promotes the differentiation, survival, and function of mast cells (Galli, Zsebo, and Geissler, 1994). Mutations in Kit have been demonstrated to occur in systemic mastocytosis in humans; these mutations lead to Kit signaling in the absence of SCF stimulation, resulting in loss of normal growth control (Longley, Reguera, and Ma, 2001). Several authors have identified the presence of Kit mutations in canine MCTs, and these also induce uncontrolled signaling (Downing et al., 2002, London et al., 1999). Although up to 30% of all canine MCTs may have Kit mutations, these are not germ line in nature (i.e., are not inherited) but occur during the process of tumor development. However, MCTs with Kit mutations exhibit higher rates of local recurrence and metastasis.

CANINE MAST CELL TUMORS

Incidence and Signalment

Mast cell tumors (MCTs) occur frequently in dogs, representing up to 20% of all cutaneous tumors (reviewed in London and Seguin, 2003). Several breeds appear to be at increased risk for the development of MCTs, including dogs of bulldog descent (boxer, Boston terrier, English bulldog), Labrador and golden retrievers, cocker spaniels, schnauzers, and shar-peis. The etiopathogenesis of MCTs in the dog is unknown, as is the reason for the extremely high incidence in this species. Although some studies have suggested the possibility of a viral cause, there is no epidemiologic evidence to indicate horizontal transmission of tumors. The increased incidence of MCTs in certain breeds suggests the possibility of an underlying genetic cause, and studies are ongoing to identify these putative genetic risk factors. Interestingly, although dogs of bulldog ancestry are at higher risk for MCT development, it is generally accepted that MCTs in these dogs are more likely to be behaviorally benign. In addition, it was demonstrated recently that pugs develop multiple MCTs that behave in a benign fashion (McNiel, Prink, and O'Brien, 2006). In contrast, anecdotal evidence suggests that shar-peis develop MCTs that are biologically aggressive.

History and Clinical Signs

The overwhelming majority of MCTs in the dog occur in the dermis and subcutaneous tissue (London and Seguin, 2003). Rarely primary MCTs may present in other sites such as the oral cavity, nasopharynx, larynx, and gastrointestinal tract. Visceral MCTs involving the spleen, liver, and/or bone marrow (often referred to as disseminated mastocytosis) are usually the result of systemic spread of an aggressive primary cutaneous MCT, although this condition can occur as an independent syndrome. Cutaneous MCTs tend to occur as solitary nodules, although roughly 10% to 15% of dogs present with multiple tumors, with most found on the trunk, perineal region, and limbs. It is important to note that the clinical appearance of MCTs can vary widely from well circumscribed, raised, and firm to ulcerated and fixed to lipoma-like. They may be extremely slow growing, present for 6 months or more, or rapidly progressive. Clinical signs are often caused by the release of histamine, heparin, and other vasoactive amines. Mechanical manipulation of the tumor during physical examination can induce degranulation leading to erythema and wheal formation (Darier's sign), and occasionally an owner reports that the tumor appears to change in size over short periods of time. Gastrointestinal ulceration is also a potential complication of MCTs because of elevated levels of circulating histamine stimulating H_2 receptors on parietal cells causing increased acid secretion, resulting in vomiting, anorexia, melena, and abdominal pain.

Diagnosis and Staging

Cytologic evaluation of fine-needle aspirates is probably the easiest method to diagnose the presence of an

MCT. As mentioned previously, mast cell granules may not stain with Diff-Quik, leading to difficulty in making a definitive diagnosis by cytology in some cases. In addition, poorly differentiated malignant mast cells may contain few, if any, granules, in which case special stains may be required. Other round cell tumors that should be included in the differential diagnosis include lymphoma, plasmacytoma, histiocytoma, transmissible venereal tumor, and occasionally melanoma. Although the diagnosis can almost always be made by fine-needle aspiration cytology, excisional biopsy is required for histologic grading of the tumor. It is important to note that, because wide surgical excision is the treatment most likely to cure the majority of MCTs, every effort should be made to obtain a definitive diagnosis via cytology before surgical intervention. Moreover, since any cutaneous tumor may potentially be an MCT and dogs with this disease may have multiple tumors, fine-needle aspiration should be performed on all masses before removal. If cytologic diagnosis proves difficult, a needle or punch biopsy of the tumor can be obtained before surgery.

Any MCT is capable of metastasis, and it is therefore recommended that dogs be staged to determine the extent of their disease and overall health. A minimum database (complete blood count [CBC], biochemical profile, urinalysis) should be part of the workup. Dogs with MCTs (especially those with systemic disease) may have eosinophilia as a result of chemotactic factors and IL-5 produced by the mast cells. Anemia may be present secondary to hypersplenism or gastrointestinal bleeding. Rarely mast cells may be seen on a routine CBC. For many years examination of the buffy coat for circulating mast cells was used to screen dogs with MCTs for the presence of systemic/metastatic disease. However, several studies have demonstrated that dogs with many syndromes, including pneumonia, parvovirus, pancreatitis, skin disease, and gastrointestinal diseases may have mast cells circulating in the periphery (McManus, 1999). Therefore, although easy to perform, the buffy coat is probably not a very useful diagnostic test. In the normal bone marrow mast cells are found infrequently, and as such the presence of mast cells in the marrow is indicative of systemic disease. Since it is usually easier to find evidence of systemic involvement in other organs (liver, spleen), routine bone marrow aspiration is not recommended on most patients.

All regional lymph nodes should be examined carefully for signs of enlargement, and any suspicious nodes should be aspirated for cytologic examination. In addition, since metastatic nodes may palpate within normal size, it is recommended that all accessible regional lymph nodes be examined by aspiration cytology. Mast cells may be present in normal lymph nodes, and they are often found in reactive lymph nodes; thus it may be difficult to determine if mast cells identified on cytologic examination are neoplastic or part of the normal immunologic cellular repertoire. However, malignant mast cells in metastatic lymph nodes are often found in clusters/aggregates rather than singly, aiding in a diagnosis of metastasis. If possible, lymph node aspiration should be performed before surgical removal of the MCT because postoperative inflammation can result in mast cell migration to local nodes and thus confuse the interpretation. If necessary,

ultrasound can be used to identify the local lymph node of interest to facilitate needle aspiration.

Thoracic radiographs are always indicated as part of any staging procedure, although pulmonary involvement is uncommon in dogs with MCTs. Abnormalities reported include lymphadenopathy (sternal, hilar), pleural effusion, and anterior mediastinal masses. Evaluation of the abdominal cavity is important in dogs with MCTs because spread to the liver, spleen, and other abdominal structures may be noted. Ultrasound is a more sensitive diagnostic technique for evaluation of abdominal organs than radiography. It is recommended that fine-needle aspiration of the liver and spleen be performed if abnormalities are detected in these organs during ultrasound examination or if the dog possesses negative prognostic indicators (e.g., clinical signs, rapidly growing ulcerated tumor, evidence of lymph node metastasis, high-grade tumor).

Prognosis

Canine MCTs possess a wide range of biologic behaviors, from benign to extremely aggressive, leading to metastasis and eventual death from disease. Several prognostic factors have been identified that help to predict the biologic behavior of an MCT and direct the course of therapy. The histologic grade of an MCT is usually determined after excisional biopsy of the tumor and *cannot* be assessed simply by cytologic evaluation of fine-needle aspirates. The grade of an MCT is determined by the characteristics of the neoplastic cells (e.g., degree of granulation, cytologic and nuclear pleomorphism), number of mitotic figures, and the extent of tumor invasion into the underlying tissues. Histologic grade using the system described by Patnaik, Ehler, and MacEwen (1984) is the *most consistent prognostic factor* and correlates significantly with survival, but it does not predict the behavior of every tumor.

Grade 1 tumors are considered to behave in a benign manner, and complete surgical excision is usually curative. Historically these represented between 30% and 55% of all MCTs reported (London and Seguin 2003; Patnaik, Ehler, and MacEwen, 1984). However, recently there is a trend toward fewer tumors being classified as grade 1, with most being placed in the grade 2 category.

The grade 2 tumors represent between 25% and 45% of all MCTs reported, and their biologic behavior is more difficult to predict (London and Seguin 2003; Patnaik, Ehler, and MacEwen, 1984). On histopathology they exhibit invasion into the underlying subcutaneous tissue. As a result they may be more challenging to remove by surgical excision. Many grade 2 tumors are cured with wide surgical excision; furthermore, radiation therapy (RT) following incomplete excision of solitary grade 2 MCTs can cure more than 80% of affected patients (Frimberger et al., 1997). It is important to note that grade 2 MCTs have the ability to spread to local lymph nodes, as well as distant sites, and a proportion of dogs that undergo definitive therapy (surgery and radiation) may go on to develop metastatic disease. Furthermore, some dogs that present with grade 2 MCTs already have evidence of metastatic disease, making appropriate staging imperative for these dogs. Given the wide variation in biologic behavior among grade 2 tumors, there is now an effort to identify

subcategories of grade 2 tumors that may be more likely to behave in an aggressive manner using additional prognostic indicators described later.

Grade 3 tumors represent between 20% and 40% of all MCTs, and these often behave in a biologically aggressive manner, exhibiting metastasis early on in the course of disease. The mean survival time of dogs with grade 3 MCTs has been reported as 18 weeks when treated with surgery alone. In one study the percentage of dogs with grade 3 MCTs surviving at 1500 days was reported as 6%, and in another study the percentage of dogs surviving at 24 months was 7%, indicating that these tumors are particularly malignant (London and Seguin, 2003; Patnaik, Ehler, and MacEwen, 1984). With the recent addition of postoperative chemotherapy to the treatment regimen of grade 3 MCT patients, evidence suggests that survival times may be improved.

Although a clinical staging scheme has been developed for prognostic purposes, stage (0 to IV) has not necessarily been proven to correlate with prognosis. For example, two studies demonstrated that the presence of mast cells in the regional lymph node was a negative prognostic factor for survival and disease-free interval (LaDue et al., 1998; Thamm, Mauldin, and Vail, 1999). However, an additional study revealed that dogs with grade 2 tumors and lymph node metastasis treated with RT after surgery achieved long-term survival (Chaffin and Thrall 2002). Last, although it would seem intuitive that dogs with multiple cutaneous MCTs do not do well, two separate studies have demonstrated that this does not necessarily affect prognosis (Murphy et al., 2006; Thamm, Mauldin, and Vail, 1999).

MCTs that develop in the oral cavity, nail bed, inguinal, preputial, and perineal regions were originally reported to behave in a more malignant fashion regardless of histologic grade. Two recent reports now demonstrate that, at least for MCTs in the inguinal, preputial, and perineal regions, this is likely to be untrue because dogs with tumors in these locations do not necessarily fare poorly (Cahalane et al., 2004; Sfiligoi et al., 2005). MCTs that originate in the viscera (gastrointestinal tract, liver, spleen), bone marrow, or peripheral blood carry a grave prognosis. As previously mentioned, certain breeds (pugs, Boston terriers) are more likely to develop benign MCTs, whereas others such as shar-peis are more likely to develop malignant disease. Tumors present for long periods of time (months to years) may be more likely to behave in a benign manner. In one study 83% of dogs with tumors present for longer than 28 weeks before surgery survived for at least 30 weeks, compared to only 25% of dogs with tumors present for less than 28 weeks (Bostock, 1973). The same study demonstrated that most dogs surviving for longer than 30 weeks after surgery appeared to be cured.

Several proliferative indices have been evaluated in an attempt to predict the outcome of canine MCTs. Perhaps the most useful is Ki-67, a protein found in the nucleus, the levels of which appear to correlate with cell proliferation. In one study the mean number of Ki-67-positive nuclei was significantly higher for dogs that died of MCTs than for those that survived (Abadie, Amardiellh, and Delverdier, 1999). For dogs with grade 2 tumors, the

number of Ki-67 was significantly associated with outcome. This was confirmed recently by an additional study that demonstrated that the Ki-67 score can be used to divide grade 2 MCTs into two groups with markedly different expected survival times (Scase et al., 2006). The mitotic index (MI, number of mitoses per 10 high-power fields) is often used as a prognostic indicator in other tumor types. A recent study (Romanski et al., 2007) suggests that this may be extremely useful for predicting the biologic behavior of canine MCTs. When dogs presenting with metastatic disease were excluded from analysis, those with tumors possessing an MI of 5 or less had a median survival time of 80 months compared to 3 months for those possessing an MI more than 5, suggesting that MI is a strong predictor of overall survival for dogs with MCTs.

Treatment

The choice of treatment modalities used for a particular canine MCT depends heavily on the prognostic indicators discussed previously, especially the histologic grade and clinical stage; these are summarized in Box 81-1. Wide surgical excision is indicated for all canine MCTs because, although they may feel like discrete masses, microscopically most extend well beyond the palpable borders. Historically it has been recommended that the margins need to be at least 3 cm in each direction; deep margins are as important as the lateral margins. Recent work indicates that for grade 1 or "low-grade" grade 2 tumors, the margins do not need to be as large (Simpson et al., 2004). However, clinically the diagnosis of MCT is often reached cytologically, and tumor grade is rarely known before the surgery. Because of this, it appears prudent to still recommend a 3-cm lateral margin and one fascial plane for the deep margin when feasible. All of the excised tissue should be submitted; the lateral and deep margins should be labeled accurately so the pathologist is able to specifically identify any areas of incomplete excision (see Chapter 68). However, it is sometimes difficult for the pathologist to determine if a mast cell present at the tissue margin represents a malignant or a normal cell. This is reflected in

the finding that a substantial proportion of incompletely excised MCTs do not recur. For example, in a recent study the estimated proportions of grade 2 tumors that recurred locally following incomplete excision at 1, 2, and 5 years were 17.3%, 22.1%, and 33.3%, respectively. In this study the combination of Ki-67 and proliferating cell nuclear antigen (PCNA) scores was prognostic for local recurrence, and development of local recurrence was prognostic for decreased overall survival (Seguin et al., 2006). Therefore ancillary therapies may not always be indicated in the setting of incomplete excision of grade 2 tumors.

Substantial data suggest that radiation (Chapter 67) is extremely effective at eliminating remaining microscopic disease following incomplete excision of grades 1 and 2 MCTs (greater than 90% 3-year control rate) (Al-Sarraf et al., 1996; Frimberger et al., 1997). Unfortunately dogs with grade 3 tumors do not fare as well; although RT may be effective at preventing local recurrence of tumor, many dogs eventually develop metastasis; this may be less likely to occur if chemotherapy is included in the treatment plan (see following paragraphs). RT has also been used to treat gross MCTs (macroscopic disease) when surgery was not an option. Although varying degrees of success have been reported, RT should not be used as the primary therapeutic modality if surgical intervention is an option. Coarsely fractionated or "palliative" RT has also been used to treat dogs with nonresectable high-grade MCTs. This may result in an improvement in quality of life but is unlikely to significantly increase survival time. Moreover, systemic effects of mast cell degranulation following RT may lead to vomiting, hypotension, and gastrointestinal ulceration.

The use of adjuvant chemotherapy is indicated following excision of grade 3 MCTs, metastatic MCTs, or any other MCT with negative prognostic factors. Although RT is considered the treatment of choice for incompletely excised grades 1 and 2 MCTs, evidence now suggests that postoperative chemotherapy may help to delay or prevent local recurrence (unpublished results) and therefore should be considered for patients who are not candidates for RT or if such therapy is unavailable or declined by the owners. In general chemotherapy for bulky MCTs has for the most part been unrewarding, and long-term responses have not been demonstrated in well-controlled clinical trials. The following drugs are used to treat MCTs.

Box 81-1

Postsurgical Treatment Recommendations for Canine Mast Cell Tumors

- Grade 1: Complete excision; no further therapy
- Grade 1: Incomplete excision; wider excision or radiation therapy if surgery not possible; may consider no further therapy
- Grade 2: Complete excision; chemotherapy only if negative prognostic factors present
- Grade 2: Incomplete excision; wider excision or radiation therapy if surgery not possible; may consider no further therapy if there are no negative prognostic indicators; chemotherapy if negative prognostic factors present
- Grade 3: Complete excision; chemotherapy
- Grade 3: Incomplete excision; chemotherapy ± wider excision or radiation therapy

Corticosteroids

The exact mechanism explaining how corticosteroids kill malignant mast cells is unknown. The reported response rate of canine MCT to prednisone is 20%, with remission times of 10 to 20 weeks. Partial remissions are more common than complete remissions, and at least some of the observed response may be because of a decrease in tumor-associated edema. This decrease is likely caused by stabilization of mast cell granules and a reduction in mast cell mediator production.

Lomustine (CCNU)

An alkylating agent that has been used to treat lymphoma and brain tumors in dogs, lomustine was recently found to have activity against canine MCT. A response rate of approximately 42% was noted when dogs with grades 2 and 3 MCTs that had failed all other therapies were treated

with lomustine (Rassnick et al., 1999). As with prednisone, most of these were partial responses, and the median duration of response was only 3 months. Additional studies suggest that lomustine given in the adjuvant setting after surgery (either alone or with prednisone and vinblastine) can significantly prolong survival times of dogs with high-grade tumors or tumors with negative prognostic indicators. It should be noted that lomustine can produce both hematopoietic and hepatic toxicity, including severe neutropenia, irreversible thrombocytopenia, and liver failure. Patients receiving this drug should be monitored *very closely*, and the lomustine should be discontinued if there is evidence of either toxicity. In general lomustine is dosed at 50 to 90 mg/m² orally every 3 to 4 weeks, with small dogs receiving doses in the lower end of the range. A CBC and liver panel should be performed before each dose.

Vinblastine

Vinblastine has been reported to have efficacy against canine MCTs. A retrospective analysis of dogs with various forms of MCTs treated with a combination of vinblastine and prednisone revealed a 47% response rate (Thamm, Mauldin, and Vail, 1999). Recent data have confirmed the potential use of vinblastine in the adjuvant setting for high-risk grade 2 MCTs in which 100% of dogs treated with prednisone and vinblastine following surgical removal of the tumor were alive at 3 years (Thamm, Turek, and Vail, 2006). The dosage of vinblastine is 2 to 3 mg/m² given every 1 to 3 weeks. The major toxicity of this drug is neutropenia, and occasional gastrointestinal upset is noted. This drug is a vesicant and thus must be given through intravenous injection. In many cases lomustine and vinblastine are administered in an alternating fashion (i.e., every 2 to 3 weeks) in combination with prednisone (Box 81-2).

Miscellaneous drugs

In limited clinical reports both L-asparaginase and chlorambucil have been found to have activity against MCTs. Small-molecule inhibitors of Kit recently have been demonstrated to have clinical activity against canine MCTs in two separate studies. These inhibitors are administered orally and act by blocking Kit phosphorylation and subsequent signal transduction. In one study a response rate of

55% was observed in dogs with MCTs treated with an oral Kit inhibitor (London et al., 2003). As expected, most of these responses occurred in dogs with MCTs possessing Kit mutations. Additional clinical work with Kit inhibitors is ongoing, and evidence suggests that they may be particularly useful for dogs with tumors exhibiting Kit mutations.

Animals with large primary MCTs, evidence of metastatic disease, or systemic signs should be treated with medications to block some or all of the effects of histamine release. To prevent gastrointestinal ulceration, any of the standard H₂ antagonists may be used, including cimetidine, ranitidine, or famotidine. Alternatively proton pump inhibitors such as omeprazole may be used; these inhibitors are probably more useful in the setting of gross mast cell disease in which standard H₂ antagonists may be less effective. Mast cell degranulation can lead to hypotensive shock and death, consequently patients with gross mast cell disease should be placed on the H₁ antagonist diphenhydramine.

Box 81-2

Chemotherapy Protocol for Canine Mast Cell Tumors

Day 1: CBC; vinblastine 2 mg/m² IV; begin prednisone 1 mg/kg PO SID for 7 days, then EOD for maintenance (can reduce to 0.5 mg/kg EOD)
 Day 14: CBC; chemistry panel; lomustine 50-70 mg/m² PO
 Day 21: CBC at nadir; if no neutropenia noted, do not need to repeat after then next Lomustine
 Day 28: CBC; Vinblastine 2 mg/m²
 Day 42: CBC; chemistry panel, lomustine 50-70 mg/m² PO; continue for a total of 6 months.
 CBC, Complete blood count; EOD, every other day; IV, intravenously; PO, orally; SID, once a day.

CHAPTER 82

Malignant Melanoma*

PHILIP J. BERGMAN, *Armonk, New York*

Melanoma is a common tumor of dogs ($\approx 4\%$ of all canine tumors) and demonstrates extremely diverse biologic behavior related to a variety of identifiable factors. An understanding of these factors helps the clinician delineate the appropriate staging, prognosis, and treatment options for canine melanomas. The primary factors determining the biologic behavior of a melanoma in any given dog include site, size, stage, and histologic parameters. Unfortunately, even with an understanding of these variables, there are occasional melanomas that exhibit unreliable biologic behavior. Accordingly there is a desperate need for additional research into this relatively common, heterogeneous, but frequently malignant tumor. This chapter reviews management options for melanomas in dogs, and assumes that a diagnosis of melanoma has already been established (although this can be difficult at times). The discussion focuses on the aforementioned biologic behavior parameters, staging, and treatment of canine melanoma.

BIOLOGIC BEHAVIOR

The biologic behavior of canine melanoma is extremely variable and best characterized based on anatomic site,

size, stage, and histologic parameters. On divergent ends of the spectrum would be a 0.5-cm haired-skin melanoma with an extremely low grade, likely to be cured with simple surgical extirpation, versus a 5-cm high-grade malignant oral melanoma with a poor-to-grave prognosis. Similar to the development of a rational staging, prognostic, and therapeutic plan for any tumor, two primary questions must be answered: what is the local invasiveness of the tumor and what is the metastatic propensity? The answers to these questions will determine the prognosis, and to be discussed later, the treatment.

SITE

The anatomic site of melanoma is highly, although not completely, predictive of local invasiveness and metastatic propensity. Melanomas involving the haired skin that are not in proximity to mucosal margins often behave in a benign manner. Surgical extirpation through a lumpectomy is often curative, but histopathologic examination is imperative for delineation of margins as well as a description of cytologic features. In haired-skin melanomas exhibiting histopathologic criteria of malignancy, the reader is referred to the grade discussion that follows.

Oral and/or mucosal melanoma routinely has been considered an extremely malignant tumor with significant local invasiveness and high metastatic potential. This biologic behavior is very similar to human oral and/or mucosal melanoma. Melanoma is the most common

*The fields of veterinary tumor immunotherapy and veterinary oncology and I personally are greatly indebted to the tireless work and seeds laid by the late Dr. Greg MacEwen; he is greatly missed, and this chapter is dedicated to him.

oral tumor in the dog; additional common neoplastic differentials include squamous cell carcinoma, fibrosarcoma, and epulides/odontogenic tumors.

For canine oral/mucosal melanomas with histologic reporting suggestive of a benign lesion, the reader is referred to the grade discussion that follows. The anatomic sites that split the prognostic spectrum of generally benign-acting haired-skin versus typically malignant and metastatic oral/mucosal melanomas include those melanomas located on the digits or foot pads. Dogs with melanoma of the digits but without lymph node or further metastasis are reported to have median survival times of ≈ 12 months when treated with digit amputation. Of these 42% to 57% are alive at 1 year and 11% to 13% alive at 2 years. Unfortunately metastasis from digit melanoma at presentation is reported in 30% to 40% of cases, and the aforementioned outcomes even with surgery suggest that distant metastasis is common even when no metastasis is found at initial presentation. The prognosis for dogs with melanoma of the foot pad has not been reported previously. I have found this anatomic site to be similar in metastatic propensity and prognosis to digit melanoma. Interestingly, human acral lentiginous melanoma (plantar surface of the foot, palms of the hand, and digit) has an increased propensity for metastasis compared with cutaneous melanoma of other sites.

SIZE AND STAGE

For dogs with oral melanoma, primary tumor size has been found to be prognostic. The World Health Organization (WHO) staging scheme for dogs with oral melanoma is primarily based on size: stage I, less than 2cm-diameter tumor; stage II, 2cm- to less than 4cm-diameter tumor; stage III, 4cm or larger tumor and/or lymph node metastasis; and stage IV, distant metastasis. MacEwen and colleagues (1986) reported median survival times (MSTs) for dogs with oral melanoma treated with surgery to be approximately 17 to 18, 5 to 6, and 3 months with stages I, II, and III disease, respectively. More recent reports suggest that stage I oral melanoma treated with standardized therapies, including surgery, radiation, and/or chemotherapy, have an MST of approximately 12 to 14 months, with most dogs dying of distant metastatic disease, not local recurrence.

A number of limitations can be identified with the present WHO staging scheme for canine oral melanoma. First, the size of the tumor is not standardized to the size of the patient. Therefore a 1.8-cm oral melanoma without lymph node metastasis is a stage I melanoma in a rottweiler and in a Chihuahua. Further investigations with standardization to patient size are needed. In addition, the histologic appearance and other histologically based indices of melanomas are not accounted for in the present WHO staging scheme, and unfortunately proposed alternate schemes incorporating histologic criteria have not gained traction in management of canine melanoma. For these and other reasons, investigators have pursued other prognostic factors in canine oral melanoma with the intent of developing alternative staging systems. These investigations have substantiated that size is highly prognostic, but have also identified the following *negative*

prognostic factors: conservative extirpation and incomplete surgical margins; location (caudal mandibular and rostral maxillary do more poorly); tumor mitotic index higher than 3; and bone invasion/lysis. Prospective investigations, including these variables into an expanded WHO staging system, are needed.

The staging system for canine nonoral melanoma is remarkably less well defined to date. Henry and colleagues (2005) used the WHO tumor, node, metastasis (TNM) system for canine digital tumors, which defines T1 as a tumor smaller than 2cm and superficial, T2 as a tumor 2 to 5 cm with minimum invasion, T3 as a tumor larger than 5 cm or invading subcutis, and T4 as a tumor invading fascia or bone. They reported that metastasis-free interval was inversely associated with T stage across all digit tumors. When specifically examining dogs with digit melanoma, there was one dog with T2, five dogs with T3, and four dogs with T4 tumors. Further studies defining staging schemes for canine nonoral melanoma with clinical variables and outcomes are also encouraged.

GRADE AND HISTOLOGIC PARAMETERS

Histopathologic grading of a tumor by the pathologist delineates degree of malignancy. Grading systems vary across tumor types. The histologic grade is commonly predictive of survival, metastatic rate, and other clinical variables in a wide variety of tumors across species, including canine melanoma. For example, in haired-skin melanomas exhibiting multiple histopathologic criteria of malignancy (high mitotic rate, invasiveness, or poor differentiation), metastatic propensity is increased, and the prognosis is worse. Bostock (1979) reported that 45% of dogs with malignant skin melanomas died within 1 year, whereas 8% of dogs with "benign" skin melanomas died from their disease. Furthermore, 10% of dogs with haired-skin melanoma with a mitotic index of 2 or less died from their tumor 2 years after surgery compared to more than 70% of dogs that died from a tumor with a mitotic index of 3 or more. Dogs with haired-skin melanomas within 1 cm of mucosal margins have been minimally investigated to date; I have seen multiple patients with histologically benign, haired-skin melanoma within 1 cm of a mucosal margin develop subsequent distant metastatic disease.

The most exhaustive review of histologic findings in canine melanocytic neoplasms was published by Spangler and Kass (2006). In this paper 384 dogs with melanoma or melanocytoma had their tumors comprehensively histologically examined and statistically tested for association with malignant behavior (recurrence and/or metastasis) and MSTs via follow-up provided by the veterinarians submitting the samples. Significant *negative* prognostic factors included metastasis (i.e., stage as discussed previously); size/tumor volume; and a variety of histologic criteria such as mitotic index, nuclear atypia, tumor score, presence of deep inflammation, intralesional necrosis, and junctional activity. As expected, these investigators also found three primary anatomic-location mortality groups: (1) oral (19% of samples), (2) feet and mucosal surface of lips (19% of samples), and (3) cutaneous (59%

of samples). Too few ocular melanomas were investigated to make recommendations.

An unexpected finding from this investigation was the presence of 32% of dogs with oral melanoma without malignant behavior according to their criteria (no recurrence, no metastasis, and alive at the end of study or dead from competing causes). I see no reason why oral melanomas may not occasionally behave in a benign fashion; however, 32% is a significantly different enough frequency from all previous reports (which report a very small proportion to benign oral melanomas) to warrant additional study. Similarly, the number of benign-acting oral melanomas was relatively small ($n = 22$); and a variety of factors, such as lack of necropsy, standardization of follow-up, lack of reporting of number of lost to follow-up cases, and, last, the large number of cases disqualified for inclusion because of poor differentiation, may have led to an increased frequency of benign-behaving cases. Similarly, I have seen in excess of 10 dogs in the last 4 years with a previous histopathologic diagnosis of "benign oral melanoma" presenting with florid distant metastasis. This is consistent with Bostock's report (1979) that three of seven dogs with "benign" oral melanomas eventually died of their disease.

Spangler and Kass (2006) also reported that 38% and 12% of foot/mucosal surface of lips and cutaneous melanocytic tumors, respectively, behaved in a malignant fashion. Four percent and 27% of the dogs that died of a foot/lip and cutaneous melanoma, respectively, had a tumor score that would have predicted benign behavior. On further review of those cases, no attributes were found that would allow for prediction of malignant behavior. This suggests that additional testing is needed beyond routine light microscopy for delineation of malignant versus benign behavior for canine cutaneous melanoma. Laprie and associates (2001) reported the use of Ki-67 expression via immunohistochemistry in 68 canine cutaneous melanomas. This group found that the predictive value of Ki-67 proliferative index (97%) was greater than the predictive value of classical histology (91%) for biologic behavior in canine cutaneous melanoma. This strongly suggests that the use of Ki-67 immunohistochemistry and possibly other proliferative markers (e.g., AgNOR and others) in canine cutaneous melanoma should be commonly performed after the histopathologic diagnosis is made.

STAGING

The staging of dogs with melanoma is relatively straightforward. A minimum database should include a thorough history and physical examination, complete blood count and platelet count, serum biochemical profile, urinalysis, three-view thoracic radiographs, and local lymph node aspiration cytology. Both ipsilateral and contralateral nodes should be sampled in cases of oral melanoma because of variability in draining patterns, whether lymphadenomegaly is present or not. Williams and Packer (2003) reported in dogs with oral melanoma that $\square 70\%$ had metastasis when lymphadenomegaly was present but, more importantly, $\approx 40\%$ had metastasis when no lymphadenomegaly was present. Additional considerations should be made for abdominal compartment imaging (e.g., abdominal ultra-

sound) in all cases of canine melanoma, especially in cases with potentially moderately-to-highly metastatic anatomic sites such as the oral cavity, feet, or mucosal surface of the lips since melanoma may metastasize to the abdominal lymph nodes, liver, adrenal glands, and other sites.

TREATMENT

The treatment for dogs with melanoma without distant metastatic disease on staging starts with local tumor control. This is generally best completed through surgical extirpation because of its speed, increased curative intent, and reduced cost compared to other modalities. The extent of surgery is generally based on the anatomic site of the melanoma, with cutaneous melanomas usually requiring lumpectomy and all other sites requiring more aggressive and wide excision. Although large resections such as partial mandibulectomy or maxillectomy carry an inherent level of morbidity, owner satisfaction rates are routinely 85% to 90% or greater. The importance of complete staging cannot be overstated when contemplating larger resections; the presence of distant metastatic disease would attenuate the use of more radical surgical procedures and convert the patient to medical and/or palliative care options.

Radiation therapy (RT, Chapter 67) plays a role in the treatment of canine melanoma when the tumor is not surgically resectable, the tumor has been removed with incomplete margins, and/or the melanoma has metastasized to local lymph nodes without further distant metastasis. The use of smaller fractions of RT (e.g., 3 to 4 Gy) given daily to every other day can allow for a greater total dosage and fewer chronic RT reactions; however, melanoma appears resistant to these types of fractionation schemes. Coarse fractionation schemes for canine melanoma using 6 to 9 Gy weekly to every other week to a total dosage of 24 to 36 Gy have been reported by a variety of investigators, with complete remission rates of 53% to 69% and partial remission rates of 25% to 30%. Unfortunately recurrence and/or distant metastasis were common in all of these studies. Other modalities reported for local tumor control as case reports and/or case series have included intralesional cisplatin implants, intralesional bleomycin with electronic pulsing, and many others; but widespread use has not been reported to date.

In dogs with melanoma in anatomic sites predicted to have a moderate-to-high metastatic propensity or dogs with cutaneous melanoma with a high tumor score and/or increased proliferation index through increased Ki-67 expression, the use of systemic therapies is warranted. Rassnick and colleagues (2001) reported an overall response rate of 28% using carboplatin for dogs with malignant melanoma. Unfortunately only one dog had a minimally durable complete response, and the rest were nondurable partial responses. Similarly Boria and colleagues (2004) reported an 18% response rate and an MST of 119 days with cisplatin and piroxicam in canine oral melanoma. Other reports using single-agent dacarbazine, melphalan, or doxorubicin suggest poor-to-dismal activity. More recently and importantly, two studies (Proulx et al., 2003; Murphy et al., 2005) suggest that chemotherapy plays an insignificant role in the adjuvant treatment of canine melanoma. It can be argued that the studies

performed to date to evaluate the activity of chemotherapy in an adjuvant setting for canine melanoma have been suboptimal for a variety of reasons; however, the extensive human literature in this specific setting suggests that melanoma is an extremely chemotherapy-resistant tumor. It is clear that new approaches to the systemic treatment of this disease are desperately needed.

Immunotherapy represents one potential systemic therapeutic strategy for melanoma. A variety of immunotherapeutic strategies for the treatment of human melanoma have been reported previously, with typically poor outcomes because of a lack of breaking tolerance to the “self” antigens present on the tumor cells. Immunotherapy strategies to date in canine melanoma have used autologous tumor cell vaccines (with or without transfection with immunomodulatory cytokines and/or melanosomal differentiation antigens), allogeneic tumor cell vaccines transfected with interleukin 2 or GM-CSF, liposomal-encapsulated nonspecific immunostimulators (e.g., L-MTP-PE), intralesional Fas ligand deoxyribonucleic acid (DNA), bacterial super-antigen approaches with granulocyte macrophage colony-stimulating factor or interleukin 2 as immune adjuvants, and canine dendritic cell vaccines loaded with melanosomal differentiation antigens. Although these approaches have produced some clinical antitumor responses, the methodologies for the generation of these products are expensive; time consuming; sometimes dependent on patient tumor samples being established into cell lines; and fraught with the difficulties of consistency, reproducibility, and other quality control issues.

The advent of DNA vaccination circumvents some of the previously encountered hurdles in vaccine development. DNA is relatively inexpensive and simple to purify in large quantity. The antigen of interest is cloned into a bacterial expression plasmid with a constitutively active promoter. The plasmid is introduced into the skin or muscle with an intradermal or intramuscular injection. Once in the skin or muscle, professional antigen-presenting cells, particularly dendritic cells, are able to present the transcribed and translated antigen in the proper context of major histocompatibility complex and costimulatory molecules. Although DNA vaccines have induced immune responses to viral proteins, vaccinating against tissue-specific self-proteins on cancer cells is clearly a more difficult problem. One way to induce immunity against a tissue-specific differentiation antigen on cancer cells is to vaccinate with a xenogeneic (different species) antigen or DNA that is homologous to the cancer antigen. It has been shown that vaccination of mice with DNA-encoding cancer differentiation antigens is ineffective when self-DNA is used, but tumor immunity can be induced by orthologous DNA from another species.

At the Animal Medical Center in collaboration with human melanoma investigators at Memorial Sloan-Kettering Cancer Center (MSKCC), we have chosen to target defined melanoma differentiation antigens of the tyrosinase family. Tyrosinase is a melanosomal glycoprotein, essential in melanin synthesis. Immunization with xenogeneic human DNA-encoding tyrosinase family proteins induced antibodies and cytotoxic T-cells against syngeneic B16 melanoma cells in C57BL/6 mice, but immunization with mouse tyrosinase-related DNA did not induce detectable immunity. In particular, xenogeneic DNA vac-

cination induced tumor protection from syngeneic melanoma challenge and autoimmune hypopigmentation. Thus xenogeneic DNA vaccination could break tolerance against a self tumor differentiation antigen, inducing antibody, T-cell, and antitumor responses. We have investigated the use of human tyrosinase, murine gp75, murine tyrosinase, and murine tyrosinase with or without human GM-CSF in dogs with advanced malignant melanoma (Bergman et al., 2003 and 2006). The results of these trials demonstrate that xenogeneic DNA vaccination in canine malignant melanoma: (1) is safe, (2) leads to the development of antityrosinase antibodies (Liao et al., 2006), (3) is potentially therapeutic, and (4) is an attractive candidate for further evaluation in an adjuvant, minimal residual disease phase II setting. To this end our research group and industrial sponsor are presently completing a multisite U.S. Department of Agriculture safety trial of human tyrosinase DNA vaccination in dogs with locoregionally controlled stage II/III malignant melanoma and have received conditional licensure for commercial sale of this product in April 2007. The efficacy portion of this trial is ongoing and human trials of MSKCC using murine and human tyrosinase DNA vaccination are also ongoing.

At the time this chapter was written, there were three sites pursuing active immunotherapy trials for canine melanoma in North America: the Animal Medical Center, the University of Wisconsin-Madison (UW-Madison),* and the University of Florida.† Although a number of immunotherapy approaches for melanoma and other tumors have been investigated, the present UW-Madison approach for canine melanoma immunotherapy is with a whole-cell allogeneic tumor cell vaccine (ATCV). The canine melanoma cell line 17CM98, developed by G. Hogge and associates, is electroporated with human GM-CSF cDNA. Each ATCV aliquot is 2×10^7 transfected cells given intradermally once weekly $\times 4$ and then every other week $\times 2$ and monthly $\times 3$. The present approach at the University of Florida is a GD3 ganglioside (tumor-associated carbohydrate antigen expressed on tumors of neuroectodermal origin such as melanoma and small-cell lung carcinoma) vaccine with MPL adjuvant and CpG motifs. There were no side effects with this vaccine in normal dogs and no side effects to date in the 13 dogs accrued with resectable gross melanoma receiving three monthly vaccines.

In summary, the future is looking brighter for canine melanoma on multiple fronts. We have a greater understanding of the prognostic aspects of this disease, and there is now a commercially available vaccine for treatment. It is hoped in the future that this same vaccine may also play roles in the treatment of melanoma in other species (e.g., horses, cats, humans) because of its xenogeneic origins and in melanoma prevention once the genetic determinants of melanoma risk in dogs are further defined. Veterinary oncologists are in a unique position to contribute to advances in both canine and human melanoma, in addition to other cancers with similar comparative aspects across species.

CHAPTER 83

Anal Sac Tumors

RUTHANNE CHUN, *Madison, Wisconsin*

Anal sac adenocarcinomas (ASACs) are relatively rare tumors in dogs and extremely rare in cats. German shepherd dogs are consistently overrepresented in the literature, as are golden retrievers. Other canine breeds at risk for ASAC include cocker spaniels and English springer spaniels. Contrary to earlier reports, several recent studies identify a 1:1 male:female ratio. The single case report of a cat with ASAC involved a neutered male Siamese cat. Differential diagnoses for animals presenting with a suspected ASAC include anal sac abscess; other anal sac neoplasms such as squamous cell carcinoma; or other perineal neoplasia such as perianal adenoma, perianal adenocarcinoma, or occasionally mast cell tumor (see also Chapter 122 on Anal-Rectal Disease).

HISTORY AND CLINICAL SIGNS

The majority of dogs are presented for examination because of visible perianal swelling. Other client concerns include tenesmus, licking or biting at the perianal area, stranguria, scooting, or hind limb weakness. Tenesmus may be caused by a large primary tumor or because of large sublumbar or intrapelvic lymph nodes. Nonspecific

complaints from owners of dogs with ASAC include polyuria and polydipsia (PU/PD), lethargy, and anorexia. The most common cause of PU/PD in this population is hypercalcemia of malignancy secondary to tumor production of parathyroid hormone-related peptide (see Chapter 74). Up to 50% of dogs may have no reported problems, and an anal sac mass is found on routine physical examination.

PHYSICAL EXAMINATION FINDINGS

Physical and careful rectal examinations reveal a mass in the anal sac. Tumor size varies at the time of presentation from 100 cm² or larger to less than 1 cm². Rarely bilateral ASAC may be detected. In addition to identifying the anal sac mass, rectal examination may allow for detection of enlarged intrapelvic lymph nodes. In small dogs or dogs with significant enlargement, sublumbar lymphadenomegaly may also be identified either on rectal examination or abdominal palpation. An interesting phenomenon reported in dogs with metastatic ASAC is the finding of a small primary tumor with very large metastatic regional lymph nodes. Animals may also have fecal impaction.

DIAGNOSTIC EVALUATION

Tissue Diagnosis

Fine-needle aspirate of the anal sac mass is well tolerated and easy to perform. The anal sac is isolated between the thumb and forefinger via rectal palpation, and the needle is introduced through the perineal tissues. Sedation is rarely required for this procedure. Cytologic findings compatible with malignancy include the finding of basophilic epithelial cells with a high nuclear-to-cytoplasmic ratio, anisokaryosis, and nuclear moulding. Specific criteria for the cytologic diagnosis of ASAC have not been described. However, this quick and inexpensive diagnostic test rules out anal sac abscess and supports further diagnostic testing.

A biopsy is required for definitive diagnosis of ASAC. For very large masses an incisional biopsy is appropriate. For smaller anal sac masses, anal saccullectomy may be performed. Owners should be cautioned that a second surgery may be recommended if adequate surgical margins are not achieved through excisional biopsy. The surgeon should have a complete understanding of the surgical anatomy, including regional innervation and blood supply.

Minimum Database

The majority of dogs with ASAC are older, and since treatment of these tumors involves surgery and possibly radiation and chemotherapy, a minimum database is important. This generally includes a complete blood count, serum chemistry profile, and urinalysis. In addition, paraneoplastic hypercalcemia is present in up to 30% of dogs with ASAC. If hypercalcemia is present, careful attention should be paid to the calcium:phosphorus product. If it is higher than 60, soft-tissue mineralization and renal failure may be an issue. Further, if the hypercalcemia exceeds 18 mg/dl or if the patient has muscle fasciculations, bradycardia, or other cardiac arrhythmias or neurologic signs such as lethargy, coma, or seizures, aggressive therapy should be initiated immediately. For information on management of hypercalcemia (see Chapters 52 and 54).

Staging Tests

Dogs with ASAC present with identifiable metastasis to regional lymph nodes in 36% to 96% of cases; lung metastases are recognized in 10% to 25% of cases. Thus staging should include three-view thoracic radiographs and abdominal ultrasound examination. Pulmonary nodules, as opposed to a more reticular pattern, are the typical radiographic pattern of lung metastasis with ASAC. Llabres-Diaz (2004) reported that increased size or number of detected lymph nodes or finding rounder or sonographically heterogeneous lymph nodes could differentiate normal lymph nodes from neoplastic lymph nodes. Even if these nodes are not enlarged, an attempt should be made to sample palpable or visible regional lymph nodes via needle aspirate. Because ASAC can also metastasize to bone, in particular the lumbar vertebrae,

abdominal radiographs that include the vertebral column are also recommended.

BIOLOGIC BEHAVIOR

As indicated previously, ASAC are highly metastatic and locally invasive tumors. Small primary tumors can be associated with bulky metastatic lesions. The presence of hypercalcemia is a poor prognostic factor if it cannot be controlled pharmacologically or by resolution of the underlying tumor. Dogs can be managed relatively long term for obstructive rectal lesions; but, if they have uncontrollable hypercalcemia, their outlook is poor.

TREATMENT

Combination Therapy Is Ideal

Surgery Alone

As with any solid tumor, surgical resection is the mainstay of treatment. Because sublumbar or intrapelvic lymphadenomegaly can adversely impact quality of life, cytoreductive surgery of these nodes is appropriate when they are enlarged. Intrapelvic nodes are difficult to remove without splitting the pelvis; and clients should be informed of the additional morbidity associated with this procedure. Omentalization of a cystic metastatic sublumbar lymph node has been reported to prolong survival time in a dog that was significantly symptomatic for a caudal abdominal mass. Unfortunately the majority of metastatic lymph nodes are not cystic, and lymph node extirpation is required for effective palliation.

Large tumors that require 180-degree or greater anoplasty are associated with a higher postoperative complication rate. Postoperative infection and fecal incontinence are the most common complications. Tumors larger than 10 cm² are also associated with shorter survival times compared to dogs with smaller tumors. With surgery alone, recurrence rates of approximately 50% have been reported. Bennett and colleagues (2002) documented a median disease-free interval of 10 months in dogs treated with surgery alone. Median survival of dogs treated only with surgery ranges from 7.9 to 16.7 months. In a large retrospective study Williams and associates (2003) found that dogs treated with surgery (with or without radiation therapy or chemotherapy) had significantly longer survival than dogs that did not have surgery. Adjuvant therapy appears to prolong survival (see following paragraphs).

Surgery and Radiation Therapy

Postoperative radiation therapy has been evaluated to a limited degree. Turek and associates (2003) described 15 dogs treated with postoperative radiation therapy (15 fractions of 3.2-Gy delivered Monday through Friday for 3 weeks) and mitoxantrone chemotherapy (5 mg/m² q21d intravenously [IV]). Both the sublumbar lymph nodes and the primary site were treated in 12 dogs; in 3 dogs only the perineal site was treated. Although the median survival time was 31.9 months, both acute and chronic radiation complications were common and contributed to euthanasia decisions in two cases. It is likely that smaller fractions over a longer time period would be

better tolerated. Radiation therapy as the sole treatment modality has not been reported.

Surgery and Chemotherapy

Surgery combined with chemotherapy also has been reported. A retrospective study by Emms (2005) discussed the outcome of 14 dogs treated with cytoreductive surgery followed by melphalan chemotherapy ($7 \text{ mg/m}^2 \times 5$ days, q3wks PO) for an indefinite number of cycles. All of the dogs had local excision of the anal sac with a 1-cm margin; seven dogs also had the sublumbar lymph nodes removed because of palpable lymphadenomegaly. Median survival time of these 14 dogs was 20 months, and there was no significant difference in survival time between dogs with and without lymph node metastasis. Median disease-free interval was not reported. Other reports of dogs treated with surgery and adjuvant chemotherapy are harder to interpret since chemotherapy protocols and extent of disease at the time chemotherapy was initiated varied significantly.

Chemotherapy Alone

Chemotherapy alone may be contemplated for palliation of patients when surgery is not possible because of location or extent of disease. Chemotherapy as the sole treatment modality is associated with a median survival time of 7 months. Although nothing more than short-lived partial remissions have been reported, agents with activity against ASAC include actinomycin-D (0.7 to 0.9 mg/m^2 q3wks IV), cisplatin (70 mg/m^2 q3wks IV), carboplatin (300 mg/m^2 q3wks IV), and doxorubicin (30 mg/m^2 q2-3wks IV).

Palliative Treatments

Dogs with owners that decline definitive therapy may continue to have a reasonable quality of life for weeks to months, as long as hypercalcemia can be managed. I recommend pamidronate (1 to 2 mg/kg in 250 ml 0.9% NaCl IV over 2 hours q28d) as the most effective drug to manage chronic hypercalcemia. Although corticosteroids

are less expensive, they are less effective and have more side effects than monthly pamidronate. After hypercalcemia, the main issue affecting quality of life is whether the animal can defecate. The stool can be kept soft through the judicious use of lactulose (1 ml/4.5 kg q8h orally) and/or psyllium (1 tsp to 2 Tbsp per day mixed into the food) titrated to effect and a low-residue diet. Owners must be instructed to monitor their pet's ability to defecate, urinate, and ambulate comfortably. Skeletal or pulmonary metastases may become more of an issue than rectal obstruction, and quality of life should be discussed.

Hypoallergenic Diets for Dogs and Cats

Cyclosporine Use in Dermatology

CRAIG E. GRIFFIN, *San Diego, California*

INTRODUCTION AND INDICATIONS

Cyclosporine has been evaluated in dogs and introduced into the veterinary field as the drug Atopica (Novartis). Atopica is approved for treating canine atopic dermatitis. The manufacturer has performed, supported, and published numerous and extensive studies in cyclosporine therapy in dogs. Many of these investigations have been summarized in several review articles (Guaguere et al., 2004 and Steffan et al., 2004). Cyclosporine is the first alternative therapy to glucocorticoids that has shown similar efficacy to prednisolone and methylprednisolone. Since its release cyclosporine has also been evaluated or anecdotally reported as effective for a variety of allergic and cutaneous diseases of dogs and cats (Table 84-1). This list continues to grow, and the drug has been tried in most glucocorticoid-responsive and idiopathic inflammatory disorders. A major drawback to its use is the cost, which many clients consider prohibitive, especially in medium- to large-sized dogs. For this reason, many practitioners do not stock Atopica, or they limit its use to small dogs and cats. Alternate dosing methods are suggested in this chapter. These regimens are designed to minimize the drug cost to clients. I believe practitioners should consider cyclosporine as an alternative treatment option in dogs and cats for the dermatologic conditions listed in Table 84-1.

CYCLOSPORINE FORMULATIONS

Different cyclosporine formulations are available and include both human brand name products and generic formulations. Two main types of formulations available are an emulsion and a microemulsified form. The microemulsified formulations generally are better absorbed. Atopica is a microemulsion concentrate that is absorbed quickly and more effectively through the gastrointestinal tract of dogs than nonmicroemulsified formulations. Although absorption is better with Atopica, it is still somewhat erratic, and bioavailability varies from 23% to 45%. Presence of food in the gastrointestinal tract increases the range of bioavailability and can reduce absorption by up to 20%; however, other dogs have increased absorption, especially when the diet is high in fat. Currently the only veterinary-approved product is Atopica, which may be more convenient than the human and generic formulations because it is available in a wider range of capsule sizes (10 mg, 25 mg, 50 mg, and 100 mg). Some generic formulations have a warning on the label stating a lack of bioequivalence; and it has been my experience that some

dogs do not respond as well to generic formulations or they only respond at a higher dose, which generally offsets any cost savings. My preference is to start initial therapy with Atopica and adjust to the lowest dosage to maintain a response. Then, if the maintenance cost is considered too expensive, a generic formulation is substituted at the same dosing regimen, and the treatment response determines if the generic product can be used long term.

DOSE AND USE OF CYCLOSPORINE

Cyclosporine is most commonly given at 5 mg/kg every 24 hours. For some diseases such as perianal fistula and atopic dermatitis in cats with concurrent asthma, initial dosages as high as 7.5 to 10 mg/kg every 24 hours or 4 mg/kg every 12 hours may be used. It may take 2 to 4 weeks to see a response, and generally a 4-week trial is the minimum. Dogs that show greater than 50% response in the first 4 weeks are more likely to be maintained long term. Once a response is obtained, the dosage may then be tapered. It is best to continue the induction dosage until clinical improvement is complete or a steady state of response is reached. Tapering is achieved by maintaining the dose at 5 mg/kg but changing the treatment interval to every 48 hours for 1 month. If symptoms return, the daily dose is reinstituted until a response is again achieved; then an alternate attempt at dose reduction is tried: 2 days on and 1 day off. This method results in a 33% reduction in cost. If a favorable response is maintained after 1 month at every-48-hours dosing, the dosing is again tapered to every 72 hours. As long as improvement and control are maintained, further tapering to every 4 to 7 days may be attempted.

The Radowicz 2003 study reported that some dogs with atopic dermatitis had complete responses (for over 6 months); even once cyclosporine was discontinued these dogs maintained long-term remissions. The frequency of this response rate requires further definition, but I find that some patients can discontinue cyclosporine for months before symptoms return. Another study (Steffan et al., 2004) also showed temporary remissions once the drug was stopped. In such responsive cases, going on and then off the drug for long intervals represents yet another way to manage some patients. This approach may also keep the cost within a client's comfort level. Some dogs can be maintained on relatively low levels of cyclosporine long term by first tapering the dose and the going off the drug for extended periods. In these cases, when it does become necessary to reintroduce cyclosporine, it is often possible to rapidly taper to a maintenance dosage.

Table 84-1

Cyclosporine Cutaneous Indications

Specific Disease/Syndrome	Dog	Cat
Allergic Diseases		
Atopic dermatitis	X	X

Urticaria pigmentosa		X

Another approach that may allow a dosage reduction is based on altering the metabolism of cyclosporine, which is predominantly metabolized by cytochrome P-450 3A12 enzyme primarily in the liver. Drugs that decrease this enzyme result in an increase in blood levels of cyclosporine. Ketoconazole specifically inhibits hepatic microsomal cytochrome P-450 3A12 enzyme and is the most common drug used to allow a reduction in cyclosporine dose. Ketoconazole, 5 mg/kg orally, is given as frequently as cyclosporine, approximately 8 to 12 hours before cyclosporine administration. This results in many dogs responding to a lower dose of cyclosporine in the range of 2 to 4 mg/kg. Since not all dogs respond to the cyclosporine/ketoconazole combination, it is still preferable to initiate therapy first with cyclosporine at 5 mg/kg. After a response is obtained and a maintenance dosage is established, ketoconazole is then added to allow further tapering of the drug dosing. When clients with large

dogs are reluctant to use the recommended dose because of cost, the initial therapy can be a combination of ketoconazole and 2.5 mg/kg of cyclosporine. However, clients should be warned that the response rate could be poorer using this protocol.

CYCLOSPORINE ADVERSE REACTIONS

Adverse reactions have been reported in two large studies by Steffan, Parks, and Seewald (2005) and Steffan, Favrot, and Mueller (2006). Based on these studies, other reports, and my experience, the most commonly encountered side effects are vomiting and diarrhea, which occasionally can result in owners discontinuing therapy. In the 2006 Steffan, Favrot, and Mueller review of cyclosporine use in 672 atopic dogs, 25% had vomiting, and 15% had soft stools or diarrhea, which usually occurred within the first month. Dogs that vomit should have the drug administered with food, and often after several days the drug can then be administered on an empty stomach without problems. If vomiting recurs, cyclosporine should be given with a fatty meal on a long-term basis. However, this may interfere with drug absorption. Concurrent administration with ketoconazole in some dogs also induces vomiting when cyclosporine alone is tolerated. Sometimes concurrent use of metoclopramide, 0.2 to 1 mg/kg every 24 hours, may allow continued use of Atopica. Management of diarrhea involves temporarily stopping the drug and then treating again with the addition of metronidazole or fiber (such as pumpkin or psyllium husk) to the diet. In spite of these therapies, gastrointestinal signs are still the most common adverse reaction that causes cessation of therapy.

Other side effects seen with some frequency include hirsutism and gingival hyperplasia. Hirsutism is characterized by a generalized thickened dense hair coat often associated with increased shedding. In other cases there are patterns in which the hair growth is exceptionally long. The patterns most commonly seen or at least recognized include hirsutism of the paws, especially interdigital hair growth, as well involvement of the head or face. The gingival hyperplasia often requires discontinuation of therapy, although rare cases may have lesion regress by temporarily stopping the drug, followed by resuming it at a lower dose. Some cases of gingival hyperplasia are associated with bacterial overgrowth and respond to systemic antibiotic therapy. Papillomatous hyperplasia is infrequently seen, and usually the lesions are negative for papilloma virus. Cytology should be performed whenever lesions occur and when bacteria are seen; antibiotic therapy and cyclosporine dose reductions usually eliminate the lesions. Bacterial infections are always a concern and may also appear as atypical lesions. Bacteruria may also be found, but a true relation to cyclosporine therapy has not been established. Bacteruria occurs less commonly with dogs taking cyclosporine than in canine dermatologic cases treated with long-term glucocorticoids.

Infrequent or rare reactions may also be observed. Increased pruritus is uncommon, but cases have been observed in which the cyclosporine has been associated with moderate-to-intense pruritus on provocation testing. If pruritus increases after cyclosporine therapy

is initiated, it may take some trials to determine if the cyclosporine is the cause, if the underlying disease is becoming more severe, or if secondary microbial infections are developing. There are anecdotal reports of upper respiratory infections in cats taking cyclosporine. Fatal toxoplasmosis has been reported in cats; this has led to some clinicians recommending that all cats being tested before beginning therapy. Atypical systemic fungal and aspergillosis infections have been seen in a limited number of cases and most commonly have occurred in dogs treated with concurrent high-dose glucocorticoids. A relatively high incidence of nephrotoxicity and hepatic toxicity is reported in humans but has not been observed in dogs and cats, although elevations in creatinine levels have been reported in dogs. When creatinine elevations occur, they do not typically progress into abnormal levels during the first year of therapy. Elevated liver enzymes are more prevalent when ketoconazole is given concurrently either for *Malassezia* or as a dose-sparing agent. While rare in dogs, elevated blood pressure is another major concern of cyclosporine therapy in humans. It is recommended that blood pressure should be monitored periodically in dogs and cats taking this drug. In humans there is also an increased risk for malignancy, especially skin neoplasia, with cyclosporine therapy; however, this relationship has yet not been documented in dogs.

MONITORING

Routine monitoring of serum levels of cyclosporine for therapy of skin disease is not recommended because serum levels generally do not correlate with clinical responses. However, there may be some value in monitoring levels when clinical responses are not observed. If serum levels are still in the low nontherapeutic range, dosages can be increased in an attempt to obtain a

response. The most important indication for monitoring is when adverse effects such as skin lesions, hirsutism, and gingival hyperplasia occur. These adverse effects may be dose related, and follow-up evaluations are recommended. Baseline biochemistry and urine evaluations should be evaluated when cyclosporine is used as a long-term therapy.

Physical examinations initially at 3 months and then at least once every 6 months are recommended. One should pay close attention to the gingiva, skin, and hair coat. Even though organ dysfunction is uncommon, regular monitoring is prudent since long-term experience with cyclosporine is still limited. Complete blood counts, chemistry profiles, urinalyses, and blood pressure testing are indicated at a frequency of 4 to 12 months. In cases having increasing creatinine levels, monitoring every 4 months is warranted at least until values have stabilized.

Interferons

TOSHIROH IWASAKI, *Tokyo, Japan*

Interferons (IFNs) belong to the class of cellular proteins referred to as cytokines. These proteins are secreted by cells of the immune system in response to viral infection or neoplasia. IFNs exert inhibitory effects on viral and cell proliferation and affect the immune regulatory system and inflammatory reactions. Recently IFNs have been used in a number of trials for treatment of atopic dermatitis in dogs.

CLASSIFICATION

IFNs are classified as either type I or type II. Type I IFNs bind to the cell via the INFA receptor. Type I IFNs are further classified as either α , β , or ω . IFN- γ is the only cytokine classified into type II IFN. Mature IFN- γ forms a homodimer that binds to the IFN γ -receptor complex by which it exerts its effect.

Recombinant feline IFN- ω and recombinant canine IFN- γ are only available in a few countries, but various types of recombinant human IFNs are more widely available. In Japan natural human IFN- α has been approved for the treatment of bovine diarrhea. There have been no clinical trials conducted to study IFN- α efficacy in treating small animal skin diseases.

MODE OF ACTION

IFNs are antiviral and also possess antioncogenic properties. IFNs are directly induced by the presence of viruses; and when large amounts of double-stranded ribonucleic acid (RNA) are found within the cell in association with Toll-like receptors, IFNs are synthesized and secreted to surrounding cells. IFNs are also induced by other cytokines such as interleukin (IL)1, IL2, IL12, and tumor necrosis factor.

IFN- α and IFN- β are produced by various types of cells, including lymphocytes, macrophages, and fibroblasts. They also activate macrophages and natural killer lymphocytes and directly inhibit tumor cell proliferation. IFN- γ is produced by activated Th1 cells and has an immunomodulating effect on Th1/Th2 cytokine balance.

CLINICAL APPLICATION OF INTERFERONS IN SMALL ANIMAL DERMATOLOGY

Interferon- α and Interferon- β

There are a number of anecdotal reports on the treatment of animal skin diseases using recombinant human IFN- α 2b (rHuIFN α 2b) and IFN- α 2a (rHuIFN α 2a). In one published report rHuIFN α 2b was used for the management of

idiopathic recurrent canine pyoderma at a dosage of 1000 units/ml/day and was found to provide transient benefits compared with placebo (Thompson et al., 2004). rHuIFN α was administered at a dosage of 1,000,000 units/kg subcutaneously three times a week for 2 weeks to treat canine papillomavirus-associated hamartoma and squamous cell carcinoma, but the efficacy of these therapies is uncertain (Callan, Preziosi, and Mauldin, 2005).

Interferon- γ

Recombinant canine IFN- γ (rCaIFN γ) is produced by silkworms via the transfer of canine full-length IFN- γ genes. It was launched on the Japanese market for the treatment of canine atopic dermatitis in 2005. Six subcutaneous injections of rCaIFN γ given in 2 consecutive weeks modified Th1 and Th2 cytokine messenger RNA profiles such as IL4 and IFN- γ toward Th1 cytokine predominance. Treatment showed improvement of clinical signs in 10 atopic dogs (Iwasaki et al., 2005). It also decreased total immunoglobulin (Ig)E in sera, although allergen-specific IgE was not determined.

Recently a randomized clinical trial for rCaIFN γ was performed in 92 atopic dogs by subcutaneous administration at a dosage of 10,000 units/kg three times a week for 2 weeks, followed by once-a-week administration for 2 weeks. The rCaIFN γ group showed 72% efficacy, whereas the control group given antihistamine spray showed 20% efficacy (Iwasaki and Hasegawa, 2006).

A placebo-controlled, double-blinded study was conducted by Hasegawa, Sakurai, and Iwasaki (2004) using the same protocol as the previous study used for treating atopic dogs. A 58% decrease in lesion size was determined using a computer-assisted imaging analyzer evaluation compared to the 38% decrease in the placebo group. Based on these clinical studies the manufacturer recommends a dosage of rCaIFN γ of 10,000 units/kg, given subcutaneously three times a week for the first 4 weeks, followed by once-a-week injections for the next 4 weeks. Although the mode of action of this drug has not yet been clarified, modification of the Th1 and Th2 cytokine profiles may play some role in the improvement of clinical signs in canine atopic dermatitis. Only a few side effects, including pain at the injection site, were noted.

Interferon- ω

Recombinant IFN- ω (rFeIFN ω) produced by silkworms has been launched in Europe and Japan for the treatment of feline calicivirus and canine parvovirus infections. Recently Carlotti and associates (2004) reported the

efficacy of rIFN ω against canine atopic dermatitis. They administered rFeIFN ω to 20 atopic dogs at a dosage of 1,000,000 units/kg subcutaneously three times a week for 3 weeks and found a 60% decrease of clinical scores at day 42. Sieback and colleagues (2006) examined the effects of both rFeIFN ω and recombinant human IFN- α (rHuIFN α) on in vitro replication of feline herpes virus 1. When given at a higher dosage, rFeIFN ω showed stronger inhibition of viral replication than rHuIFN α , indicating the efficacy of rFeIFN ω against feline herpes virus infection.

CHAPTER 86

Avermectins in Dermatology

AMANDA BURROWS, *Murdoch, Western Australia*

AVERMECTINS IN DERMATOLOGY

The avermectin class of antiparasitic agents includes two distinct chemical families: avermectins (ivermectin, abamectin, doramectin, eprinomectin, salinomectin, and selamectin) and milbemycins (moxidectin and milbemycin oxime). These are important antiparasitic agents because of their wide spectrum of activity, high potency, safety margins, and unique mechanism of action. Each member exerts a similar mode of antiparasitic action, but there is variation in efficacy, which is presumed to relate to differences in the chemical structure. Avermectins and milbemycins are closely related macrocyclic lactones produced naturally as fermentation by-products of actinomycetes from the genus *Streptomyces*. In veterinary dermatology the avermectins and milbemycins of importance are ivermectin, selamectin, and doramectin and milbemycin oxime and moxidectin, respectively. There is a wide use of these compounds for management of parasitic diseases. Despite the clinical evidence for therapeutic efficacy and safety, many of the clinical indications and dosage regimens recommended for avermectins in

dogs and cats are extra-label or unapproved. Accordingly, the veterinarian is wise to secure written owner informed consent before embarking on an extra-label course of therapy.

Mechanism of Action

Avermectins and milbemycins have two modes of action. The primary mode of action is selective, high-affinity binding to specific glutamate gated chloride channels in synapses between inhibitory interneurons and excitatory motor neurons in nematodes and in myoneural junctions in arthropods. These compounds also enhance the release of γ -aminobutyric acid (GABA) in presynaptic neurons, which in turn opens postsynaptic GABA-gated chloride channels. In either case the influx of chloride ions reduces cell membrane resistance, which prevents the potential hyperpolarisation of neural stimuli to muscles, resulting in flaccid paralysis and death. Mammals, unlike nematodes and arthropods, have GABA-mediated interneuronal inhibitors only in the central nervous system. It is believed that the mammalian blood-brain barrier is

impermeable to the avermectin class drug; thus toxicity in mammals occurs at a much higher concentrations compared with nematodes and arthropods.

IVERMECTINS

Ivermectin

Ivermectin is a derivative of avermectin B1 and licensed in small animals only for the prevention of dirofilariasis at a dosage of 6 to 12 mcg/kg once a month orally. The ivermectin formulation most commonly used in dogs and cats for the extralabel treatment of ectoparasites in veterinary dermatology is available commercially as a 1% non-aqueous injectable solution formulated in 60% propylene glycol and 40% glycerol (Ivomec, Merial Animal Health). This can be diluted with sterile propylene glycol for accurate dosing for kittens and small dogs; however, propylene glycol can be irritating when administered subcutaneously and can cause bradycardia and respiratory and central nervous system depression. For this reason some veterinary dermatologists prefer to use the aqueous 0.8% oral drench approved for use in sheep and goats (Ivomec Liquid, Merial Animal Health), which can be administered undiluted or diluted with sterile water. The oral solution of ivermectin must be given by mouth, whereas the injectable propylene glycol-based formulation can be administered subcutaneously or orally. A 0.5%, alcohol-based pour-on ivermectin formulation (Ivomec Pour-on, Merial Animal Health) approved for use in cattle has been used in dogs and cats. Ivermectin is sensitive to ultraviolet light and should be stored in the dark or dispensed in an opaque bag to prolong its shelf life.

Ivermectin has a wide margin of safety in dogs and cats; however, an increased susceptibility to acute toxicity is evident in a subpopulation of collie and collie-type dogs. The oral dose of ivermectin shown to cause adverse effects in noncollie dog breeds is in the range of 2,500 to 10,000 mcg/kg. In contrast, clinical signs of toxicity develop after the administration of only 100 mcg/kg in the subpopulation of susceptible breeds. Clinical signs include mydriasis, depression, ataxia, hypersalivation, bradycardia, hyperthermia, apparent blindness, decreased menace response, muscle tremors, and disorientation, which may progress to weakness, recumbency, unresponsiveness, stupor, and coma. Acute ivermectin toxicity has been reported in other breeds, including Australian shepherds, Shetland sheepdogs, Old English sheepdogs, Dobermans, and their crossbreeds. This idiosyncratic toxicity is associated with the homozygous expression of a four-base pair deletion mutation of the multidrug resistant (MDR-1) gene in collies and Australian shepherds.

The MDR-1 gene encodes a large transmembrane protein forming an integral part of the blood-brain barrier, p-glycoprotein. P-glycoprotein plays an important role in integrity of the blood-brain barrier by limiting drug uptake into the brain. Altered expression or function of p-glycoprotein may allow elevated brain concentrations of ivermectin and thereby potentiate neurotoxicity. Whether other affected breeds have the same MDR-1 mutation is unknown. A commercial polymerase chain reaction (PCR)-based method for MDR-1 genotyping using canine

deoxyribonucleic acid (DNA) from mouth cells is available for detecting the mutation in dogs and should be considered if ivermectin must be used in potentially susceptible breeds. Information is available at the Washington State University Veterinary Clinical Pathology website: www.vetmed.wsu.edu/depts-vcpl/test.asp. Recently a rapid PCR-based method that can discriminate between homozygous and heterozygous alleles using a small amount of genomic DNA from a blood sample has been developed (Geyer et al., 2005). Further studies are awaited to clarify the reliability of this test for large-scale screening and to define the frequency of the MDR-1 mutation in dog breeds. Acute ivermectin toxicity in adult cats is rare, but kittens are susceptible to the toxic effects of ivermectin; and lethargy, ataxia, coma, and death have been reported after administration of a single 300 mcg/kg subcutaneous injection.

Safety in administering oral ivermectin may be improved but not ensured by beginning with a low test dose and increasing the amount administered over several days until the desired dose is reached. In our dermatology clinic we initially administer 100 mcg/kg orally, and then we increase the dosage to 200, 300 mcg/kg, etc., every 48 hours orally in an effort to identify ivermectin-sensitive dogs. Owners are instructed to observe the pet closely over this period and to cease administration if symptoms of lethargy, incoordination, or mydriasis develop. Because of the relatively long half-life of ivermectin, serum concentrations of ivermectin administered daily continue to increase before reaching equilibrium at much higher levels than with weekly therapy. Thus chronic toxicity caused by cumulative therapy may develop with prolonged daily ivermectin treatment. In this light it is recommended that dogs receiving ivermectin be checked regularly for evidence of clinical signs suggestive of chronic toxicity; in our dermatology clinic we reevaluate dogs every 4 weeks for the first 3 months of treatment and then every 3 months thereafter.

Adverse reactions to ivermectin have been encountered with the rapid destruction of the microfilariae of *Dirofilaria immitis* in dogs. Most reactions are mild; occur within 1 to 4 hours of administration; and manifest as ataxia, vomiting, and dyspnea. However, anaphylactic shock has been observed and is more likely to occur when the microfilaria counts are high. Dogs should be screened for heartworm infection before ivermectin administration, particularly in heartworm-endemic regions.

Selamectin

Selamectin is a derivative of the avermectin endectocide doramectin. It is available as a solution (6% or 12%) in an isopropyl alcohol and dipropylene glycol methyl-ether vehicle (Revolution, Pfizer Animal Health). It is licensed for topical application at a dose of 6 mg/kg for dogs and cats not less than 6 weeks of age for the treatment and prevention of fleas (*Ctenocephalides* spp.), sarcoptic (*Sarcoptes scabiei*) and otodectic (*Otodectes cynotis*) mites, ascarids (*Toxocara* spp.), hookworms (*Ancylostoma tubaeformis*) and the prevention of heartworm (*Dirofilaria immitis*). A single dorsal application on the skin at the base of the neck in front of the scapulae is recommended. If the

volume of the total dose exceeds 3 ml, the manufacturer recommends that the dose be divided among multiple areas in the dorsal neck region.

Extensive safety studies have shown that selamectin has a wide margin of safety when administered to dogs and cats, including puppies and breeding animals. The drug is safe for topical administration in ivermectin-sensitive breeds and in dogs and cats with dirofilariasis. The likelihood of accidental oral ingestion is reduced by dorsal application at the base of the neck, but inadvertent oral consumption of selamectin causes only mild salivation and intermittent vomiting in cats and no reaction in dogs.

Doramectin

Doramectin is a relatively newer semisynthetic avermectin licensed as an endectocide for subcutaneous administration in cattle, sheep, and swine (Dectomax, Pfizer Animal Health). It is not licensed for use in dogs and cats, but its extralabel use as an endectocide in these species has been widely reported. It is available commercially as a 1% solution formulated in a 90:10 volume:volume sesame oil and ethyl oleate vehicle for subcutaneous injection in the lateral midline of the back as a single dose. It is well tolerated without pain or inflammatory reaction at the injection site. In ruminants and in equine species doramectin expresses higher bioavailability and persistent efficacy when compared with ivermectin; however, recent studies indicate that this is not the case in the dog. Doramectin generated a significantly lower plasma concentration when compared to ivermectin following oral administration in the dog, whereas no significant differences were observed following subcutaneous administration (Gokbulut et al., 2006). This suggests that different formulations of doramectin for oral and subcutaneous administration may need to be developed for the dog.

There is little reported information on the safety of doramectin in dogs and cats. Some avermectin-sensitive breeds in my dermatology referral practice have displayed clinical signs of salivation, mydriasis, vomiting, tremors, ataxia, and depression when doramectin was administered at doses between 200 and 400 mcg/kg by single subcutaneous injection. Recently similar toxicity was reported in a collie dog following the single subcutaneous administration of 200 mcg/kg (Yas-Natan et al., 2003). Caution should be exercised with the administration of doramectin to potentially avermectin-sensitive breeds. I recommend that clinicians take precautions similar to those for ivermectin administration (i.e., the dose of doramectin should be increased with each weekly injection, beginning at a test dose of 50 to 100 mcg/kg). No toxic reactions have been recorded in cats.

MILBEMYCINS

Milbemycin Oxime

Milbemycin oxime is a semisynthetic derivative of milbemycin A3/A4 and is licensed for use in dogs as a prophylactic against *D. immitis* and for control of gastrointestinal parasites (Interceptor Spectrum, Novartis) at a dosage of 500 mcg/kg administered every 30 days from 4 weeks of age orally. It is available in some countries as a tablet containing milbemycin oxime 23 mg in combination with

praziquantel 228 mg. Milbemycin oxime used to be available as a single ingredient (Interceptor, Novartis), but unfortunately this product recently has been discontinued.

Milbemycin oxime has a very wide margin of safety in dogs. Mild signs of lethargy have been reported when the drug was administered at the extralabel dosage rate of 2 mg/kg every 24 hours orally, with transient, reversible signs of toxicity (stupor, trembling, and ataxia) observed at higher dosages of 3.8 mg/kg every 24 hours orally. Some avermectin-sensitive collies treated with 5 mg/kg of milbemycin oxime developed transient depression, and all collies treated with 10 mg/kg of milbemycin oxime exhibited ataxia and depression resolving within 24 hours of administration (Tranquilli, Paul, and Todd, 1991). These findings support the generally wide safety margin of milbemycin oxime. However, because occasional patients still develop neurologic adverse effects, particularly at higher doses, thorough client education and appropriate monitoring are indicated, especially in breeds at risk. Treatment of heartworm-infected dogs with milbemycin oxime is not recommended because of the development of mild transient hypersensitivity reactions. There are no reports of side effects using milbemycin oxime in cats.

Moxidectin

Moxidectin is a semi-synthetic milbemycin derivative of nemadectin. It is available as an oral tablet licensed for the prevention of canine heartworm at a dose of 3 mcg/kg once a month and a 1% or 2.5% topical spot on formulation combined with 1% or 10% imidacloprid (Advocate, Bayer Animal Health). This is licensed for application at the dosage of 0.1 ml/kg every 30 days for the treatment and prevention of gastrointestinal parasites and the prevention of heartworm (*Dirofilaria immitis*) in dogs and cats, sarcoptic (*Sarcoptes scabiei*) mites and biting and sucking lice (*Trichodectes canis*, *Linognathus setosus*) in dogs, otodectic (*Otodectes cynotis*) mites in cats and generalized demodicosis (*Demodex canis*) in dogs (Europe and Australia). A single dorsal application on the skin at the base of the neck in front of the scapulae is recommended. If the volume of the total dose exceeds 4 ml, then the manufacturer recommends the dose is divided among multiple areas in the dorsal neck region. The formulation used most commonly in dogs and cats for extralabel use in veterinary dermatology is a 1% injectable solution licensed for use in cattle (Cydectin, Fort Dodge Animal Health).

Evaluation of moxidectin has a wide margin of safety in dogs. The oral dose of moxidectin shown to cause adverse effects in noncollie dog breeds is in the range of 2000 to 4000 mcg/kg. There was no evidence of toxicity when ivermectin-sensitive collies were administered oral moxidectin doses up to five and 30 times the recommended dose of 3 mcg/kg for heartworm prevention (Paul, Tranquilli, and Hutchens, 2000); however, the safety of higher moxidectin dosages in ivermectin-sensitive collies has not been evaluated. Transient ataxia, lethargy, inappetence, and vomiting have been reported in noncollie breeds administered 200 to 400 mcg/kg every 24 hours orally for the treatment of generalized demodicosis. Recently severe neurotoxicity, including ataxia, crawling, acoustic, and tactile hyperexcitability was reported in an Australian shepherd with a homozygous MDR-1 mutation after the administration of a single dose of

moxidectin 400mcg/kg orally (Geyer et al., 2005). There are no reports of side effects or moxidectin toxicity in the cat.

COMMON USES OF AVERMECTINS IN VETERINARY DERMATOLOGY

Sarcoptic Mange

Sarcoptic mange is a highly contagious, nonseasonal, pruritic skin condition caused by infestation with the burrowing mite *Sarcoptes scabiei*. Several macrocyclic lactones (e.g., ivermectin, milbemycin oxime, oral and topical moxidectin, and selamectin) have been used successfully for the control of canine sarcoptic mange. With the exception of selamectin and topical moxidectin, these drugs are not licensed for this purpose, and the clinician should obtain informed consent from the client before beginning treatment.

Ivermectin can be administered by subcutaneous injection, orally, or topically. Although experimental reports indicate that a single subcutaneous dose of 200mcg/kg is effective, 200 to 400mcg/kg every 7 days (orally) to 14 days (subcutaneously) for 4 to 6 weeks is more reliable. Because the mite can be highly contagious, all dogs and cats in contact with known affected animals also should be treated. The 0.5% pour-on at a dosage of 500mcg/kg twice at 14-day intervals may be a convenient and economical alternative when large numbers of animals are involved. Precautions should be taken with the use of the topical formulation in ivermectin-sensitive collies and collielike breeds.

Selamectin is licensed as a topical spot-on formulation for application at a dosage of 6 to 12mg/kg every 30 days for the treatment and control of canine scabies. Field studies conducted by the manufacturers reported comparable efficacy rates to a reference positive-control product when the drug was applied at 6 to 12mg/kg on two occasions 30 days apart. However, other dermatologists and I have observed a small number of treatment failures when using the drug according to the manufacturer's recommendations, and there is concern about the potential misinterpretation of a negative response to a therapeutic trial. Consequently many dermatologists recommend using the extralabel protocol of 6 to 12mg/kg every 14 days for three applications. This regimen is also effective against feline *Sarcoptes scabiei* infestation, although the drug is not registered for this purpose in the cat.

Milbemycin oxime at a dosage of 2mg/kg every 7 days orally for 3 or 5 weeks was effective in 71% or 100%, respectively, of treated cases of canine scabies. Although more expensive than ivermectin, milbemycin at these dosages is well tolerated in collie and related breeds and therefore is a safe alternative therapy in high-risk breeds.

Topical 2.5% moxidectin spot-on formulation is licensed for the treatment and control of canine sarcoptic mange. Field studies conducted by the manufacturers reported comparable efficacy rates to a reference positive-control product when the drug was applied at 0.1 mg/kg on two occasions 4 weeks apart. Currently there are no independent studies published to support these data. Using the 1% injectable moxidectin formulation, 90% of dogs given 0.2 to 0.25 mg/kg every 7 days for 3 to 6 weeks either orally or by subcutaneous injection were cured; but side effects such as urticaria, angioedema, and ataxia were

observed in seven dogs. Side effects appeared to occur more frequently with subcutaneous administration, and this route of administration probably should be avoided.

Injectable doramectin, 1%, has been shown to be effective in the treatment of sarcoptic mange in cattle, sheep, pigs, and Angora rabbits; but published information on its efficacy for the treatment of canine sarcoptic mange is sparse. A single subcutaneous dose of 200mcg/kg has been used without adverse effect to successfully treat notoedric mange in cats.

Otodectic Mange

Otoacariasis is caused by *Otodectes cynotis*, an obligate parasite that inhabits the ear canals of dogs and cats. Ivermectin is effective at a dosage of 0.2 to 0.4 mg/kg every 7 days when given orally. The same dosage can be administered every 14 days by the subcutaneous route. At least 3 to 4 weeks of therapy is needed. All dogs and cats in contact with affected animal should also be treated. Ivermectin solution, 1%, diluted to 1:9 with propylene glycol administered every 24 hours via the otic route for 3 weeks cured all cats in one study, although some authors suggest that topical otic application is less effective than the subcutaneous route. Topical 0.5% ivermectin pour-on at a dosage of 0.5 mg/kg (0.1 ml/kg) twice at 14-day intervals is also effective.

Selamectin is licensed at the registered dose rate for the treatment and control of *Otodectes cynotis* in cats based on the results of controlled field trials by the manufacturer. An independent, uncontrolled trial using selamectin to treat naturally acquired feline otoacariasis failed to detect any mites within 17 days of treatment, although some cats had residual erythema and/or pruritus after testing negative for mites. Most dermatologists recommend the use of selamectin at 6 ml/kg at 14-day intervals for three applications for the treatment of otoacariasis, although the drug is not registered at this dose.

Topical 1% moxidectin is licensed for the treatment and control of otoacariasis in cats and kittens, and field studies conducted by the manufacturers reported 100% efficacy when the drug was applied at 0.1 mg/kg on two occasions 4 weeks apart. Currently there are no independent studies available to verify these data. Oral or subcutaneous moxidectin at 0.2 mg/kg has been shown to be effective in dogs when given twice at 10-day intervals, but reinfestation occurred in cats when a single subcutaneous injection was administered.

Cheyletiellosis

Cheyletiellosis is caused by the surface dwelling parasites *Cheyletiella blakei*, *Cheyletiella parasitovorax*, and *Cheyletiella yasguri* in dogs and cats. Currently there are no veterinary products licensed for treatment of cheyletiellosis. Affected animals can be treated with oral or injectable ivermectin at 200 to 300mcg/kg at 7- (orally) to 14- (subcutaneously) day intervals for 6 to 8 weeks, providing the owner gives informed consent. Topical pour-on 0.5% ivermectin resolved infestation when applied to cats at 14-day intervals for four treatments. Ivermectin applied by this route was generally well tolerated, but a few cats developed a transient, alopecic patch and mild scaling at the site of application.

Selamectin may provide a safer alternative for the treatment of canine and feline cheyletiellosis, although the drug is not licensed for this purpose. In one study selamectin was effective in resolving infestation in cats when applied topically at a dosage of 6 mg/kg once a month for three applications, whereas 6 to 12 mg/kg applied topically at 14-day intervals for four applications achieved a successful outcome in dogs (Mueller, 2002).

In dogs milbemycin oxime has been shown to be effective in the control of cheyletiellosis when given at 2 mg/kg every 7 days orally for 3 weeks. However, a relapse in several dogs necessitated repeating the course of treatment.

Demodicosis

Canine demodicosis is a common skin disease encountered in veterinary practice. Ivermectin at a dosage of 300 to 600 mcg/kg every 24 hours orally is recommended for the treatment of generalized demodicosis. Although there are anecdotal reports that weekly subcutaneous administration of ivermectin is effective, the reported evidence strongly suggests a lack of efficacy using this dosing regimen. Ivermectin administered at a reduced dosage interval of 450 to 600 mcg/kg every 48 hours orally can be effective in some dogs, but treatment is generally required for a longer time period. Topical 0.5% pour-on ivermectin solution is ineffective.

Milbemycin oxime administered at a dosage of 2 mg/kg every 24 hours orally is very effective for the treatment of generalized demodicosis, but unfortunately the current lack of a commercially available product that can be safely administered on a daily basis has made this therapeutic option less viable. Moxidectin at a dosage of 200 to 400 mcg/kg every 24 hours orally is another milbemycin that has been evaluated in several studies for the therapy of canine demodicosis. Side effects reported include reversible ataxia, lethargy, inappetence, and vomiting. Although more studies are required to identify the safety of moxidectin in ivermectin-sensitive breeds, I believe, particularly in the absence of milbemycin, that oral moxidectin is a useful option in some dogs that cannot tolerate ivermectin administration. Topical 2.5% moxidectin is registered for the treatment of demodicosis at a dose of 0.1 ml/kg at 4-week intervals applied for two to four treatments. Although the manufacturer data report a reduction in mite numbers of 98% in dogs treated with this dosage regimen, mites were present in a significant proportion of dogs at the end of the study. Many dermatologists believe that topical 2.5% moxidectin at the registered dosages is not effective for the treatment of canine generalized demodicosis, and further studies are needed to ascertain whether the extralabel application of this product may improve the efficacy of treatment.

Doramectin has been used successfully for therapy of canine and feline generalized demodicosis in one study at a dosage regimen of 600 mcg/kg every 7 days subcutaneously (Johnstone, 2002). None of the animals in this study showed any adverse effects. Further investigations are needed to evaluate the usefulness of doramectin, and in my opinion caution should be exercised with the use of doramectin in ivermectin-sensitive breeds.

Fleas

Selamectin has adulticidal, larvicidal, and ovicidal effects against *Ctenocephalides felis* and is the only avermectin or milbemycin with any activity against flea infestation. Selamectin administered at the registered dose rate eliminates fleas between 12 and 24 hours after application in cats and between 24 and 36 hours after application in dogs. In multicenter field trials conducted by the manufacturer, selamectin applied at the registered dosage rate for 3 months reduced flea counts on day 30, 60, and 90 by 92.1%, 99%, and 99.8% in dogs and by 92.5%, 98.3%, and 99.3% in cats.

Ticks

Ivermectin reportedly has been used to treat tick infestation with *Ixodes ricinus* in cats, but I do not find ivermectin useful for tick control in dogs. Selamectin is registered for the control of *Rhipicephalus sanguineus* and *Dermacentor variabilis* in dogs at 6 to 12 mg/kg every 30 days, but most dermatologists use selamectin applied at 14-day intervals for three applications and then once a month for tick control, despite the fact that the drug is not registered at this dosage.

Lice

A single injection of ivermectin at a dosage of 200 mcg/kg subcutaneously or a single application of topical selamectin at 6 mg/kg is effective at eliminating biting lice *Trichodectes canis* in dogs and *Felicola subrostratus* in cats. Neither drug is registered for this purpose.

Fur mites

A single injection of ivermectin at a dose of 300 mcg/kg subcutaneously is effective at eliminating *Lynxacarus radovskyi* infestation in cats.

Hypoallergenic Diets: Principles in Therapy

HILARY A. JACKSON, *Glasgow, Scotland*

INDICATIONS AND USE OF HYPOALLERGENIC DIETS

Hypoallergenic diets are designed primarily for the diagnosis and management of adverse reactions to food ingredients in dogs and cats. There are also additional indications for their use in the patient with dermatologic disease. The following definitions are used in this discussion.

- Adverse food reaction: Any clinically abnormal response attributable to the ingestion of food or food additive
- Food intolerance: An abnormal physiologic response to food with no immunologic basis
- Food allergy: An immunologically mediated adverse food reaction

The ideal hypoallergenic diet used in the diagnosis and management of adverse food reactions should contain a protein source that is either novel to the animal under treatment or in a form that does not incite an adverse immunologic, pharmacologic, or toxicologic response. Commercially available diets generally are designed for the management of true food allergy, although the incidence of immunologically mediated disease in the dog and cat is currently unknown. In humans most food allergies are mediated by immunoglobulin (Ig)E antibodies and are most common in infants and young children (Sampson, 2004). Many food allergens have been characterized at the molecular level in humans, whereas those inciting specific reactions in dogs and cats are unknown. Food allergens are generally glycoproteins with a molecular weight greater than 10,000 kD, and they are stable to digestive processes. Molecules smaller than this are less likely to bridge two IgE molecules on the mast cell surface and incite degranulation, one of the first events in type one hypersensitivity reactions (Taylor et al., 1987).

The currently available commercial hypoallergenic diets contain either novel or hydrolyzed proteins with added carbohydrate and nutrients to balance for long-term feeding. It is assumed that it is the dietary protein that is allergenic, although there is a report of dogs with spontaneous food allergy reacting to cornstarch (Jackson et al., 2003). Whether this was a reaction to the carbohydrate itself or to traces of protein from the carbohydrate source is unknown and a high percentage of infants allergic to cow's milk will have adverse immunological and clinical reactions. This chapter considers a number of key issues related to hypoallergenic diets (see Section V on Evolve).

HYDROLYZED PROTEIN DIETS

Hydrolyzed protein diets have been available for many years in the human field, specifically for the management of infants with milk allergy. They consist of hydrolyzed (digested) protein and are available in two forms: partial and complete hydrolysates. These formulations have been subject to rigorous study in infants with proven cow's milk allergy. Before a claim for hypoallergenicity can be made, the complete hydrolysate formula should be demonstrated to be tolerated by 90% or more infants with milk allergy in double-blinded placebo-controlled conditions (Baker et al., 2000). The protein in complete milk protein hydrolysates is in the form of free amino acids and peptides less than 1500 kD. In contrast, the milk proteins in partially hydrolyzed formulations are not as extensively hydrolyzed (Rugo, Wall, and Wahn, 1992).

The hydrolyzed veterinary diets available at the time of this writing would be classified as partial hydrolysates (Table 87-1). There are a number of published studies supporting the use of veterinary hydrolysate diets for diet trials in dogs. A limitation in the recommendation of their use in veterinary patients is a lack of data documenting whether dogs allergic to the parent protein can tolerate the hydrolyzed product. Nestle Purina Veterinary Diets HA HypoAllergenic brand Canine Formula (Nestle Purina PetCare) containing hydrolyzed soy protein and cornstarch has been evaluated in two small studies in dogs with pruritic skin conditions. A randomized blinded feeding study demonstrated a reduction in pruritus in soy- and corn-allergic individuals of 50% and 80%, respectively, when fed this diet (Beale and Laflamme, 2001). When HA Formula was fed to Maltese-beagle mixed breed dogs with food allergy at North Carolina State University, 11 of 14 dogs with soy and/or corn allergy showed no adverse reaction (Jackson et al., 2003). In neither of these studies was the nature of the adverse food reaction truly known, although there is evidence that the disease in the Maltese-beagle mixed breed dogs may be mediated in part by IgE. In addition, these diets are recommended for the treatment of canine and feline adverse food reactions based on the assumption that most adverse food reactions in these species are mediated by IgE, as they are in humans. Since this is not necessarily the case, the size of the protein hydrolysate may not be critical, or paradoxically hydrolysis could enhance uptake and presentation to the immune system.

Table 87-1

Currently Available Hydrolyzed Diets As of 2008*

Name of Diet	Protein Hydrolysate	Carbohydrate	Formulation	Species
Purina veterinary diets HA hypoallergenic brand canine formula ¹	Soy	Cornstarch	Dry kibble	Canine
Purina veterinary diets HA hypoallergenic brand feline formula ¹	Soy, chicken	Rice	Dry kibble	Feline
Royal Canin Hypoallergenic DR21 ²	Soy, poultry	Rice	Dry kibble	Canine
Royal Canin Hypoallergenic DR25	Soy, poultry liver	Rice	Dry kibble	Feline
Prescription diet canine z/d low allergen ²	Chicken	Rice	Dry kibble	Canine
Prescription diet canine z/d ULTRA allergen free ³	Chicken	Cornstarch	Dry kibble	Canine
Prescription diet feline z/d low allergen ³	Chicken	Rice	Dry kibble	Feline
Prescription diet feline z/d ULTRA allergen free ³	Chicken	Cornstarch	Canned	Feline
Prescription diet canine z/d ULTRA allergen free ³	Chicken	Cornstarch	Canned	Canine

*The availability of diets may vary with geographic region and formulations may be subject to change.

HOME-COOKED DIETS

Home-cooked diets are often advocated when performing a diet trial, thus avoiding pet food additives that might have the potential to cause adverse reactions. Although additives are often incriminated as causing adverse reactions in pets, there are no well-documented reports to support this idea. Home-cooked diets usually include a single novel protein and a single carbohydrate source, which have been selected on the basis of a good dietary history. An analysis of home-cooked diets in use by members of the American Academy of Veterinary Dermatology showed that these invariably were nutritionally inadequate for maintenance or growth (Roudebush and Cowell, 1992). Balanced recipes for home-cooked diets are available in various veterinary textbooks (Roudebush 1994; Remillard et al., 2000). The use of home-cooked diets may lead to poor client compliance because of the added effort required in diet preparation. The importance of client education cannot be overemphasized. In one study 36% of clients preparing home-cooked food for their dogs discontinued the diet trial prematurely (Tapp et al., 2002). Another investigator documented a failure rate of 52% of cases when the clients were asked to prepare home-cooked diets for their dogs; the failure rate dropped to 27% after better client education was instituted (Chesney, 2002).

There are reports of animals tolerating home-cooked diets but not a commercial equivalent (White, 1986; White and Sequoia, 1989; Jeffers et al., 1991). The reasons for this are unknown but may be related to differences in the processing of the proteins that can change form when heated and render them more or less allergenic. Food additives or the presence of vasoactive amines in commercial diets might also be causative (Roudebush, 2000). There has been recent interest from the pet-owning public in the feeding of raw meat diets to their pets. There is no justification in the use of these diets from the standpoint of diagnosis or management of the pet with food allergies. Furthermore, the use of these diets raises significant public health concerns related to the high bacterial burden often present on raw meat (see Chapter 37).

Whichever type of diet is used, the diet selected should be based on a thorough dietary history. This should include details of the main diet but also any treats, table scraps, and flavored toothpaste or toys to which the animal is exposed on a regular basis. Clients often hide pills in food for ease of administration of medications to their pets; thus, if therapy concurrent with the diet trial is prescribed, this practice must be discontinued. Cost and palatability are also important factors to consider. The protein in the diet should be one to which the animal has had little or no previous exposure. Unfortunately many of the protein sources currently used in prescription diets are now used in generally available pet foods, making dietary selection more challenging. In this context the hydrolyzed diets may become more useful.

Dogs with suspected atopic dermatitis, in which a dietary component of their disease is under investigation, are often less than 1 year of age. In most cases the commercially available hypoallergenic foods support growth for the 6- to 8-week period of the diet trial. However, this may not be the case in the giant breeds, and advice from an experienced nutritionist should be sought in this situation. Hypoallergenic diets specially formulated for the growing dog are available, and these should be fed preferentially. The use of home-cooked diets in growing animals must be undertaken with great care unless balanced by an experienced veterinary nutritionist. Calcium-phosphorus ratios are often incorrect and could lead to pathologic skeletal development. In the feline patient an unbalanced home-cooked diet should not be fed for more than 3 to 4 weeks.

ADDITIONAL BENEFITS OF HYPOALLERGENIC DIETS

Since most of the commercially available hypoallergenic diets have an enhanced ω -3 and ω -6 essential fatty acid (EFA) content, they can be useful in the management of dogs with impaired epidermal barrier structure or function. Ceramide-1, which contains α -linoleic acid, is an important component of the lipid barrier in the cornified

layer of the epidermis. Thus supplementation with this ω -6 fatty acid has the potential to enhance skin health.

There is evidence that dogs with atopic dermatitis triggered by environmental allergens have structural impairment of the epidermal barrier (Inman et al., 2001), the consequences of which might be enhanced transepidermal allergen penetration, increased transepidermal water loss, and/or establishment of microbial infections. In addition, dogs with atopic dermatitis may have impaired fat absorption or increased plasma triglyceride clearance (van den Broek and Simpson, 1990); thus increased EFA intake might be beneficial in these cases and account for the clinical improvement often noted after feeding a hypoallergenic diet in the absence of proven adverse food reaction. In addition, dogs with primary or secondary disorders of cornification often benefit from the feeding of hypoallergen diet. Presumably because of increased epidermal turnover time in these diseases causing a relative EFA deficiency.

CHAPTER 88

Pentoxifylline

ROSANNA MARSELLA, Gainesville, Florida

INTRODUCTION

Pentoxifylline (PTX) is a methylxanthine derivative with multiple hemorrheologic and immunomodulatory properties. PTX is available as a generic or a brand name (Trental, 400-mg tablets). This drug has been used for almost 30 years in humans with intermittent claudication caused by peripheral and cerebrovascular atherosclerotic disease; however, the interest in veterinary medicine for PTX is relatively recent. The list of conditions for which PTX has been found to be beneficial has grown rapidly. This chapter reviews the use of PTX in small animal dermatology.

PROPERTIES OF PENTOXIFYLLINE

PTX is a nonspecific phosphodiesterase (PDE) inhibitor. Through its hemorrheologic properties, PTX changes the conformation of red blood cells and improves microcirculatory blood flow and tissue oxygenation. Aged red blood cells have rigid membranes because of reduced adenosine triphosphate levels and increased calcium. By increasing cyclic adenosine monophosphate (cAMP, the second messenger of the beta-adrenergic system), and by modulating intracellular calcium, PTX increases red blood cell deformability. Besides its effect on red blood

cells, PTX also exerts its beneficial effects on platelets by decreasing platelet aggregation and blood viscosity. Once again, this is caused by the inhibition of PDE and the decrease in cAMP degradation. It is interesting to note that PTX restores normal cAMP levels and has an effect on aggregation only in conditions in which the platelets are hyperaggregable and have altered levels of cAMP. PTX does not appear to effect normal platelets and therefore does not prolong bleeding.

PTX exerts multiple beneficial effects on the inflammatory cascade by increasing intracellular cAMP and decreasing TNF- α synthesis. Since TNF- α is a proinflammatory cytokine with a broad spectrum of actions, its decrease leads to multiple antiinflammatory effects. These include a decreased release of other proinflammatory cytokines such as interleukin (IL)-1 and IL-6, decreased leukocyte adhesion and aggregation, decreased neutrophil degranulation and superoxide release, inhibition of B cell activation (by suppressing IL-6 synthesis), and inhibition of T cell activation (through CD23 and CD26 pathway) (Bruynzee, 1995). Based on *in vitro* studies, the decrease of cytokine expression is dose dependent. The beneficial effects of PTX have been shown in numerous animal studies using models of ischemia-reperfusion and septic shock (Zhang, 1994). In these studies PTX significantly improved survival rates by both decreasing the inflammatory reaction and improving tissue oxygenation. Finally PTX also improves wound healing by increasing fibroblast collagenases and decreasing collagen production, fibronectin, glycosaminoglycans, and fibroblast response to TNF- α .

PHARMACOKINETICS

The pharmacokinetics and pharmacodynamic properties of PTX have been well characterized in human patients. PTX is rapidly and extensively absorbed after oral administration (Marsella et al., 1997). After absorption from the gastrointestinal tract, it binds to the red blood cells, where it is immediately reduced to metabolite 1 (M1). This transformation is reversible, and M1, which also binds to the erythrocyte membrane, serves as a reservoir for PTX. The other six metabolites are formed in the liver and appear in plasma soon after dosing. Extensive enterohepatic recycling occurs, and more than 90% of the absorbed drug is excreted in the urine in the form of metabolites. M1 and M5 are the major metabolites, and the plasma levels of these compounds are five and eight times greater, respectively, than the parental drug. Bioavailability in humans averages 20% to 30% and is affected by food. Excretion is almost completely urinary. M1 and M5 are present in the highest concentration in the urine, whereas no PTX is found in the urine.

Only a few studies have been done in dogs to evaluate the disposition of PTX and its active metabolites. In one study (Marsella et al., 2000) PTX was found to be rapidly absorbed and eliminated after oral administration. Peak plasma concentration for PTX (15 mg/kg) was achieved 30 minutes after oral administration. Concentrations rapidly declined, and no drug was detected after 4 hours. After intravenous administration (15 mg/kg), elimination proceeded rapidly, and no drug was detectable after 3 hours. Peak plasma concentration of M1 and M5 after intravenous and oral administration was achieved after 20 minutes and

60 minutes, respectively. Mean bioavailability after oral administration ranged from 15% to 32% among treatment groups and was not affected by the presence of food. Higher plasma PTX concentrations and apparent bioavailability were observed after oral administration of the first dose compared with the last dose during the 5-day treatment regimens. It was concluded that oral administration of PTX at 15 mg/kg resulted in plasma concentrations similar to those produced by therapeutic doses in humans and that a three-times-a-day dosing regimen was the most appropriate. No adverse effects were observed.

In another study (Rees et al., 2003) PTX was readily metabolized and bioavailable (50% \pm 26%). Both active metabolites (M1 and M5) were detectable, with M5 predominating. Human drug therapeutic concentrations (1000 ng/ml) were present for 170 \pm 24 minutes following intravenous administration and 510 \pm 85 minutes after oral dosing. This study emphasized the large variability of absorption and disposition of PTX in dogs. None of the dogs experienced any adverse effects after PTX administration. No hematologic effects were detected.

ADVERSE EFFECTS OF PENTOXIFYLLINE

In contrast to other methylxanthines, PTX has few cardiac effects. PTX can be a gastric irritant, and in humans the main adverse effect is gastrointestinal upset (e.g., vomiting and diarrhea). Other reported adverse effects in humans include angina/chest pain, agitation, dizziness, headache, and tremors. Side effects are dose related and can be decreased by lowering the dose. Dogs appear to tolerate oral PTX very well, even on an empty stomach. Gastrointestinal upset can be seen, although it is not common. I have observed some short-coated dogs that develop transient flush and erythematous macules.

INDICATIONS FOR USE IN VETERINARY DERMATOLOGY

PTX has been used for a variety of dermatologic conditions with variable success. Since several of the conditions have a waxing and waning course and many of the studies done were open studies, a scientific evaluation of the efficacy of the drug was not always possible. Nevertheless the list of dermatologic diseases for which PTX has been reported to be beneficial is quite extensive.

Dermatomyositis

Canine familial dermatomyositis is an inflammatory disease in which microvascular vasculopathy is thought to play a role. Therefore dermatomyositis was one of the first dermatologic diseases in which PTX was tried and reported to have useful effects. In the management of dermatomyositis cases PTX is usually considered as a steroid-sparing agent and rarely as the only form of treatment (Jennette, 2003). The advantage of using PTX is the better safety profile and the lack of atrophogenic properties when compared to glucocorticoids. The response to treatment is variable and typically slow (2 to 3 months). Historically a large range of dosages and treatment regimens have been suggested. Recommended dosage ranges from 200 to 400 mg

once daily or once every other day. Based on a study by Rees and colleagues (2003) it appears that 25 mg/kg twice daily resulted in positive clinical response (4/10 complete, 6/10 partial response). In that study the authors investigated whether a direct correlation could be established between concentrations of PTX and its metabolites and clinical response and concluded that, because of the variability in disposition and metabolite formation among individuals, monitoring of PTX did not offer a therapeutic advantage.

Contact Allergy

PTX has also been used with success for the prevention of clinical signs caused by contact allergy. The rationale behind the use of PTX for contact allergy is its ability to decrease the production of TNF- α , an important inflammatory mediator in this condition, to down-regulate the expression of adhesion molecules on keratinocytes, and to suppress T cell adherence to keratinocytes. PTX has been reported to suppress patch test reactions in human patients and, when taken 48 hours before exposure, either abolished or drastically decreased the development of clinical signs of contact allergy (Schwarz et al., 1993a, 1993b). The same observations appear to hold for dogs with contact allergy to plants of the Commelinaceae family. In that study PTX was able to prevent contact allergy at a dose of 10 mg/kg twice daily).

I have observed that the protective effect appears to be dose related. Clinical benefit seems to be evident after 2 days of oral therapy (10 mg/kg) and does not last for a prolonged period of time after discontinuation of therapy (1 week) (Marsella et al., 1997). Based on these clinical observations and the more recent information regarding the pharmacokinetic properties of this drug in dogs, I currently use PTX at 15 mg/kg two to three times daily to improve efficacy in severe cases.

PTX does not appear to have been studied as treatment of contact allergy once lesions have already developed. Because of the moderate antiinflammatory properties of this drug, it probably would be more effective to treat active lesions of contact allergy with glucocorticoids and use PTX as a preventive agent before exposure to the offending allergen.

Canine Atopic Dermatitis

PTX has also been used for the management of canine atopic dermatitis (AD). The rationale behind its use is that PTX is a PDE inhibitor; thus it stabilizes a variety of cells, including mast cells, and has the ability to suppress the synthesis of many proinflammatory cytokines that play a role in atopic dermatitis (e.g., TNF- α , IL-6), indirectly affecting the release of chemokines that would mediate the recruitment of leukocytes in the skin. Although we are still lacking a comprehensive understanding of the pathogenesis of this disease, all of the antiinflammatory properties of PTX have been proposed to be beneficial in patients suffering from AD.

There has been one randomized, double-blinded, placebo-controlled study that has evaluated the efficacy of PTX for the management of canine AD (Marsella and Nicklin, 2000). In that study the clinical efficacy and the effect of

4 weeks of PTX on intradermal skin test reactivity were evaluated. PTX decreased owners' and investigator's pruritus scores and investigator's erythema scores, although most dogs had residual clinical signs at the end of the trial. No suppression on immediate intradermal skin test reactivity was detected, whereas delayed reactions were decreased. It was concluded that PTX may be considered as an adjunctive treatment for canine AD, especially to reduce the frequency of administration of glucocorticoids.

Anecdotally it appears that older dogs and dogs with reactions mostly to grasses seem to have the best clinical response to PTX therapy. I tend to use this drug in geriatric dogs in which the use of glucocorticoids or cyclosporine is contraindicated. This is based on the large safety and tolerability profile of PTX in dogs, and a reported improvement in the overall cognitive function of these patients in conjunction with a beneficial effect on their skin condition. The better response in patients with mostly grass allergies is an interesting clinical observation in light of the recent observations on the importance of the epicutaneous route of allergen exposure in canine AD and the speculation that some individuals may suffer from a combination of both contact allergy and AD.

Vasculitis

PTX is commonly used as steroid-sparing agent for the treatment of vasculitis of various origins (Atzori, 1999; Milling, 1994). The most commonly used dosage is 10 to 15 mg/kg twice daily (Nichol, Morris, and Beale, 2001). This is because of the combination of its potent hemorheologic properties (which increase erythrocyte deformability, thus allowing the cells to more readily pass through compromised blood vessels) and its antiinflammatory effects. Unfortunately the onset of clinical benefit is slow, and several weeks to months may be required to observe clinical response. In human patients this time frame has been reported to range from 2 weeks to 14 months. Thus PTX is rarely used alone in the early phases of therapy. It is usually combined with glucocorticoids; this combination is hypothesized to have synergistic effect in the ability to decrease inflammation, possibly through the common ability to decrease TNF- α synthesis.

Because PTX is commonly used in combination in cases that show favorable response, it is sometimes difficult to assess the exact benefit of therapy. Nevertheless I have had several cases that were well controlled just on PTX after glucocorticoids were discontinued but would relapse if PTX were discontinued. Similarly I have seen cases that were well controlled on Trental that would relapse once switched to generic PTX. This clinical observation has raised concerns about whether generics can be considered equivalent to Trental. Unfortunately no studies have been done to investigate this question; thus no definitive recommendation can be made at this time other than to consider switching to Trental when generic formulations of PTX do not have clinical benefit.

Symmetric Lupoid Onychodystrophy

Symmetric lupoid onychodystrophy is a syndrome with multiple possible causes, including vasculitis and

immune-mediated mechanisms. For this reason PTX has been used either as sole therapy or in conjunction with other immunomodulatory treatments. In one retrospective study (Mueller, Rosychuk, and Jonas, 2003) PTX was used in six dogs. Excellent response was observed in two dogs, and a good response in two others. The remaining two patients showed no improvement. One of the dogs with an excellent response had previously not responded to treatment with doxycycline, niacinamide, and fatty acids for 4 months and then underwent spontaneous remission for 6 months. When clinical signs recurred, this dog responded rapidly to PTX. As it is for other conditions, clinical benefit is slow; thus PTX should be tried for several months before improvement can be fully assessed.

Miscellaneous Conditions

There are anecdotal reports of PTX therapy of other vasculopathies, including thrombovascular necrosis, ear pinna dermatosis, rabies vaccine-related alopecia, greyhound vasculopathy, and metatarsal fistulae of German shepherds. Similarly PTX has been tried in diseases in which necrosis is a concern such as spider bites. Because of the role of TNF- α in erythema multiforme, PTX can be beneficial in cases in which an underlying cause for erythema multiforme cannot be identified, particularly in geriatric cases that have recurrent disease. Because of its combined antiinflammatory properties and the ability to decrease fibrosis, PTX also can be considered as adjunctive therapy for dogs with lick granulomas. Another potential use for PTX could be as adjunctive therapy in canine patients diagnosed with cancer and undergoing chemotherapy to possibly counteract the negative consequence of excessive release of TNF- α .

CHAPTER 89

Glucocorticoids in Veterinary Dermatology

CANDACE A. SOUSA, *El Dorado Hills, California*

WHAT ARE THEY?

Steroids are hormones that are manufactured from and resemble cholesterol. Structurally these hormones consist of three hexane rings and one pentane ring, which collectively are known as the steroid nucleus. Steroids are produced primarily in the cortex of the adrenal gland, but other organs such as the testicles and ovaries also contribute to their production. Some of the metabolically active

substances included in this group are the sex hormones, bile acids, and cortisone.

Androgens such as testosterone and estrogens are *steroids that contain 19 carbon atoms*. *Corticosteroids* (or *corticoids*) (CSs) are 21-carbon steroid hormones that are produced by the adrenal cortex. Progesterone is secreted in minute amounts by the adrenal cortex and is also a 21-carbon hormone. The major stimulus for the adrenal cortex to synthesize and secrete steroids is *adrenocorticotrophic hormone*

(ACTH), which in turn is synthesized in and released from the pituitary gland. ACTH release is stimulated by *corticotropin-releasing factor* (CRF), produced by the hypothalamus. *Mineralocorticoids* (MCs) are CSs produced primarily in the zona glomerulosa of the adrenal cortex. They exert their greatest effect on electrolyte metabolism—sodium, potassium, and chloride in particular. The most potent naturally occurring member of this group is aldosterone. Its main actions are induction of renal tubular resorption of sodium and increased renal excretion of potassium. Its release is mediated through the renin-angiotensin feedback mechanism.

CSs that increase gluconeogenesis (i.e., cause an increase in blood sugars and liver glycogen) are called *glucocorticoids* (GCs). These are products of the inner zones of the adrenal cortex, the zonae fasciculata, and reticularis. The primary physiologic CS is *cortisol*, also termed *hydrocortisone*. At least 95% of the GC activity of the adrenocortical secretions results from the secretion of cortisol. In humans cortisol is estimated to be produced at a rate of 10 mg/day. The daily production rate of cortisol can rise tenfold in response to severe stress. In dogs daily cortisol production is 0.2 to 1 mg/kg/day. No information is available for cats.

Cortisone is the synthetic inactive form of the hormone cortisol. The active form of the hormone cortisol is formed in the liver by the action of 11 β -hydroxysteroid dehydrogenase (type 1). If an additional double bond is added to cortisone, the result is increased GC activity and a decreased rate of degradation. The product of this first synthetic change is *prednisone*, which is also an inactive GC and requires hydroxylation in the liver at the C-11 position by 11 β -hydroxysteroid dehydrogenase, converting it to *prednisolone*, the biologically active form of the hormone (Fig. 89-1). There is positive evidence that cats and probably horses may not absorb prednisone well or convert it to prednisolone in the liver, making the latter a more appropriate therapeutic choice in these species.

Methylprednisolone (Medrol, Pfizer Animal Health) is formed by the addition of a methyl group to prednisolone at C-6. This tends to decrease the salt-retaining effects and slightly increases the GC effects. When a fluorine molecule is added to hydrocortisone at the C-9 position, this results in increased GC but also marked MC activity (fludrocortisone). Further modification by methylation at C-16 results

Hydrocortisone (cortisol)

Prednisone

in the synthesis of *dexamethasone* or *betamethasone*. These latter two molecules have high GC but low MC effects.

The duration of action of synthetic GCs is determined by the structure of the drug molecule. This in turn determines potency and the dose used. Generally the larger the dose and the more potent the GC, the longer the drug will have an effect (Table 89-1). However, in the clinical situation the

Table 89-1

Comparison of Water-Soluble Glucocorticoids Used in Dogs and Cats

Generic Drug	Relative Mineralocorticoid Potency	Relative Glucocorticoid Potency (Antiinflammatory Potency)	Equivalent Dose (mg)	Plasma Half-life (hours)	Duration of Action (adrenal suppression) in Humans (hours)
Hydrocortisone	1	1	20	1	<12
Prednisone/prednisolone	0.8	4	5	(?) 1	12-36
Methylprednisolone	0.5	5	4	1.5	12-36
Triamcinolone*	0	3 - 5	4	(?) 4	24-48
Dexamethasone	0	25-30	0.75	2	>48
Betamethasone	0	25-30	0.6	(?) 5	>48
Flumethasone		30	1.5		>48

*Triamcinolone acetonide has a greater potency (approaching that of dexamethasone).

route of administration and the water solubility of the carrier substance usually are more important factors affecting the duration of action. Generally oral GCs are formulated as a free base or an ester that is digested to the free base and subsequently absorbed. Parenteral GCs (i.e., injectable) are usually esters of acetate, diacetate, sodium phosphate, or sodium succinate. The sodium phosphate and succinate esters are very water soluble and rapidly attain serum levels even when given intramuscularly (i.e., prednisolone sodium succinate, Solu-Delta-Cortef, Pfizer Animal Health). In contrast, the acetate or diacetate esters are poorly water soluble and are slowly absorbed, providing a continuous low level of GC for several days to weeks (i.e., methylprednisolone acetate, Depo-Medrol, Pfizer Animal Health). This slow absorption may greatly prolong the adrenal suppressive effects. Concern regarding adrenal suppression is the basis for the recommendation of alternate-day dosing of short-acting oral GCs when long-term treatment is needed.

HOW DO THEY WORK?

The primary role of endogenous CSs is the maintenance of homeostasis. GCs influence a variety of body functions because they affect nearly every cell in the body, altering the function of multiple systems. They exert most of their actions by binding to steroid receptors on the plasma membrane and in the cytoplasm of target cells. The complex is then transported to the nucleus, where it binds to cellular deoxyribonucleic acid and alters gene expression.

In general, GCs alter carbohydrate, fat, and protein metabolism; fibroblast proliferation (important for wound healing); the inflammatory response; electrolyte and water balance; synthesis of red blood cells; central nervous system function; gastric acid production; muscle strength and function; the immune system (especially the innate arm of the immune system); and a variety of other metabolic processes. As stated earlier, GCs seem to have some effect on almost every metabolic process.

One of the most important medical uses of CSs relates to their antiinflammatory effects. Inflammation comprises the changes in the tissue in response to injury. There are four classical signs of inflammation: pain (dolor), heat (color), redness (rubor), and swelling (tumor). When tissue injury occurs, whether it be by bacteria, trauma, chemicals, or any other phenomenon, histamine and other humoral substances are liberated by the damaged cells into the surrounding fluids. This causes an increase in local blood flow as well as the permeability of capillaries, allowing large quantities of fluid and cells to leak into the tissue. The exact mechanism of action by which GCs decrease inflammation is unknown, but they decrease or prevent tissue responses to inflammatory processes, thereby reducing the symptoms of inflammation without affecting the underlying cause.

GCs stabilize the membranes of lysosomes so they rupture with difficulty. This helps prevent the usual tissue damage and destruction that occurs when lysosomal enzymes are released. GCs also decrease the production of bradykinin, which is a potent vasodilator that also increases permeability of the capillary membrane during inflammation. GCs minimize the inflammatory response through

the action of lipomodulin, which inhibits phospholipase A₂, which normally converts membrane phospholipids into arachidonic acid (AA), a proinflammatory product. The decrease in AA limits available precursor molecules for lipoxygenase and cyclooxygenase to produce the AA-derived mediators of inflammation. Last, GCs inhibit the expression of adhesion molecules on the endothelial cells (particularly ELAM-1 and ICAM-1) and thereby interfere with the movement of leukocytes from the vasculature into inflamed tissues. This is the cause of the commonly noted leukocytosis seen with GC administration.

GCs block the inflammatory response to an allergic reaction exactly the same way that they block other types of inflammation. The basic allergic reaction between an antigen and antibody is not affected, and even some of the secondary effects of the allergic reaction such as the release of histamine still occur. However, because the subsequent inflammatory response is responsible for many of the serious and sometimes fatal effects of the allergic reaction, administration of GCs can be lifesaving.

Immunosuppression induced by CSs is not completely understood. CSs generally are considered less immunosuppressive than antiinflammatory. Prevention of inflammatory mediator release, inhibition of inflammatory cell migration to and response at the site, reduced capillary permeability, and the prevention of passage of immune complexes through endothelial and basement membranes all provide beneficial effect in treating immune-mediated diseases. The functional capacity of monocytes, macrophages, and eosinophils is decreased via inhibition of the formation of interleukins. The alteration of the movement and circulation of leukocytes may alter the immune response. The effect on the cellular arm of the immune system is more pronounced than the effect on the humoral arm. GCs have minimal effects on plasma immunoglobulin concentrations but can modulate immunoglobulin function. For example, opsonization of bacteria is inhibited.

At immunosuppressive doses (the exact dose has not been determined scientifically) GCs can induce decreased production of intracellular signaling cytokines such as interleukin (IL)-1, IL-6, tumor necrosis factor- α , interferon- γ , and granulocyte-macrophage colony-stimulating factor (GM-CSF). These are the signals that T and B lymphocytes use to communicate, and decreased production of intracellular signaling cytokines related to glucocorticoid therapy results in an alteration of the immune system at multiple stages. In general, there is a decline in the number of leukocytes at the site of infection or inflammation and an interference with their function.

GCs cause marked changes in leukocyte numbers and distribution. A mature neutrophilia is a characteristic component of a physiologic stress response as well as a response to exogenous GC treatment. Increases in circulating neutrophils occurs from a combination of an increased release of mature neutrophils from the bone marrow, decreased margination, and decreased migration of neutrophils out of the blood vessels, resulting in a prolonged circulatory half-life.

In contrast, the administration of GCs leads to a decreased number of circulating lymphocytes, eosinophils, and basophils. Lymphopenia results from a redistribution of circulating lymphocytes to nonvascular

lymphatic compartments such as the lymph nodes. Since lymphopenia is not a marked or a consistent component of the feline stress leukogram, this species is considered relatively steroid resistant.

Systemic GCs are probably the most commonly used drugs in veterinary medicine and are undoubtedly the most commonly used and abused drugs in veterinary dermatology. Their intended and appropriate use in veterinary dermatology is for their antipruritic, antiinflammatory, and immunomodulatory properties. A beneficial response is seen in animals with pruritic diseases, allergic disorders, inflammatory skin diseases, and autoimmune or immune-mediated dermatoses.

The specific GC effects that occur with their therapeutic use are summarized in Box 89-1, and need be considered, particularly if ongoing therapy will be needed. The following sections consider adverse effects and specific uses of GCs in veterinary dermatology.

ADVERSE EFFECTS

As with any other class of drugs, CSs have clear value when used to treat a disorder for which they have proven therapeutic benefit and when administered at the appropriate dose, frequency, and duration of administration. Their recognized antiinflammatory and immunosuppressive effects make them a valuable addition to veterinary medicine. There is no question that side effects occur with GC therapy. However, excessive concern for these may prevent the appropriate use of this class of drugs when they are indeed indicated. The use of CSs tends to be shunned by some practitioners who worry about iatrogenic suppression of the hypothalamic-pituitary-adrenal (HPA) axis, immune suppression, and other side effects.

The benefits of any therapy must always be weighed against the possible and/or probable side effects. It is well

recognized that the excessive use of GCs can be associated with many adverse effects. Although GCs are desired for their therapeutic effects, their antiinflammatory and immunosuppressive actions may facilitate the establishment or spread of other infectious or parasitic diseases. As a result, dogs treated with GCs have a tendency to develop secondary bacterial infections of the skin, urinary tract, or respiratory tract. Urinary tract infections have been documented in 18% (Torres et al., 2005) to 39% (Ihrke et al., 1985) of dogs treated with 0.28 to 0.8 mg/kg/day of GCs for more than 6 months.

The most serious side effects of CS are related to prolonged use of large doses, which may suppress the HPA axis. The effects of chronic elevations in GC levels are readily seen with naturally occurring hyperadrenocorticism (Cushing's disease). Unfortunately the same problems can be created by overuse of GCs by the veterinarian and/or client, even when administered on an alternate-day basis. These high levels of exogenous steroids can result in a hyperglycemia, fat redistribution and a pendulous abdomen, decreased skin elasticity, atrophy of the skin, poor wound healing, poor-quality coarse hair, alopecia (e.g., hair loss from breakage and failure to regrow), comedones (e.g., follicular plugs or blackheads), a variety of bacterial infections (especially of the bladder and skin), and even calcinosis cutis (e.g., mineral deposits in the skin). Localized dermal and adnexal atrophy following subcutaneous and occasional intramuscular repositol GCs have also been reported. If the GC used also has low MC effects, polyuria (e.g., production of an increased amount of urine) and polydipsia (e.g., drinking an excessive amount) may also be present.

In addition, GCs have effects on other body systems. Through various feedback loops they can suppress the synthesis and secretion of thyroid-stimulating hormone, follicle-stimulating hormone, prolactin and luteinizing hormone, and growth hormone. GCs have direct positive chronotropic and inotropic actions on the heart. They enhance vasoconstriction and decrease capillary permeability (including that induced by inflammation.) Blood pressure is increased. GCs also enhance lipolysis, and fatty acids are mobilized from adipose tissue; however, they also enhance appetite, which stimulates hyperinsulinemia and results in lipogenesis.

Iatrogenic secondary adrenocortical insufficiency is a side effect that can be seen after withdrawal of the GC therapy. When an animal is treated with a GC, the adrenal glands, in natural response to the effect of the exogenous GCs on the HPA axis, stop producing steroid hormones for a period of time. The duration of this suppressive effect is known to be dependent on the type of steroid and duration of treatment. However, the precise degree and length of suppression in any individual dog cannot be predicted. One intravenous injection of dexamethasone at 0.1 mg/kg, which equals approximately 3 mg/kg of hydrocortisone (cortisol) or three times the highest daily natural production, can suppress the HPA axis for 32 hours in a healthy dog (Kempainen and Sartin, 1984). In general, the longer the therapy and the higher the dose, the longer the time before natural production of steroid hormones by the adrenal gland returns. This resultant lack of endogenous (physiologic) GCs is the cause of weakness and possible circulatory collapse that can occur with cessation of exogenous GC therapy.

Box 89-1

Specific Cellular and Antiinflammatory Effects of Glucocorticoids

1. Suppress the release of CRF by the hypothalamus and ACTH by the pituitary gland (caused by negative feedback inhibition) and therefore suppress the release of CSs by the adrenal cortex
2. Reduce the number of circulating lymphocytes through redistribution and suppress T lymphocyte function
3. Reduce the number of circulating eosinophils
4. Help maintain cell membrane integrity
5. Inhibit macrophage function
6. Suppress antibody function
7. Inhibit the release of endogenous pyrogen (IL-1)
8. Depress prostaglandin and leukotriene synthesis
9. Alter the complement and kinin cascades
10. Interfere with leukocyte migration and adhesion
11. Suppress lysosomal release from neutrophils by stabilizing lysosomal membranes
12. Suppress phagocytosis
13. Reduce fibroblast activity that causes delayed healing and thinning of the skin
14. Effect enzyme actions and other cellular functions

CONTRAINDICATIONS TO THE USE OF CORTICOSTEROIDS

Because GCs cause an elevation in blood glucose, caution should be exercised when they are administered to animals with diabetes mellitus. Concurrent use with non-steroidal antiinflammatory drugs should be minimized because of the increased risk of gastrointestinal ulceration. When used together, gastric protection should be strongly considered. The use of GCs should be avoided in pregnant animals since to avoid induction of parturition. Congestive heart failure has been reported in cats as a possible side effect, likely related to effects on cardiac muscle and stimulation of water retention.

USE OF CORTICOSTEROIDS IN VETERINARY DERMATOLOGY

Cortisone and ACTH were first used to treat a variety of inflammatory dermatoses in humans in the 1950s. The major indications for their use in veterinary dermatology include treatment of allergic or pruritic dermatoses, autoimmune dermatoses, and feline eosinophilic granulomas.

Because the GCs affect every cell in the body in often beneficial but also potentially negative ways, it is important to administer these medications to produce the maximum positive effect with the fewest side effects. The use of GCs is an art that requires the clinician to skillfully integrate knowledge of patient details, the owner's care and perceptions, and the disease so that an appropriate type and dose of GC can be used. Changes and adjustment in doses and even in the type of CS used may be needed depending on the response of the disease and the adverse effects that develop. Physiologic doses of GC are those that approximate the daily cortisol production by normal individuals. In dogs daily cortisol production has been reported to be 0.2 to 1 mg/kg/day. A pharmacologic dose of GC exceeds physiologic requirements. There is no optimal dose established in the veterinary literature, and each case should be treated individually. The primary guideline is to always use the lowest induction dose necessary to gain effective control of the clinical signs for the shortest amount of time and then to taper the amount even lower if possible to maintain control of the condition. There are guidelines that serve as a good starting point. Using oral prednisone or prednisolone (or methylprednisolone) in dogs as the drug of choice, the recommendations are:

Antipruritic dosages: 0.5 mg/kg/day for 3 to 10 days; then decreased to lowest effective dosage

Antiinflammatory doses: 1 to 1.5 mg/kg/day for 7 to 10 days; then decreased to the lowest effective dosage

Immunosuppressive doses: 2 to 6 mg/kg/day for induction; then decreased as possible to maintain control of the disease

Compared with dogs, cats seem to require about twice the dose of oral GCs to achieve the same effects.

LONG-TERM USAGE OF GLUCOCORTICOIDS

The use of alternate-day therapy has been recommended to minimize adrenocortical suppression and the other side/

adverse effects of the prolonged administration of GCs. For alternate-day therapy to be successful, the administration of GCs with a duration of action of 12 to 36 hours (prednisone, prednisolone, or methylprednisolone) is necessary.

The following section presents my personal opinions regarding the generally safe dosages of GCs when used long term. There is no evidence-based formula regarding safe dosing in dogs and cats, and the disease as well as individual variation and adverse effects must be considered.

My formula for dogs is as follows. Starting with the concept that dogs manufacture 0.2 to 1 mg/kg/day of cortisol and need this to survive and using a 40-kg dog as an example:

$$40\text{ kg} \times 0.4\text{ mg} \times 365\text{ days} = 5840\text{ mg of cortisol produced/year (I chose } 0.4\text{ mg since it is on the lower side of the mid range for production)}$$

Since prednisone (or prednisolone) is considered approximately four times as potent as hydrocortisone (cortisol), dividing 5840 by 4 equals 1460 mg of prednisone. Thus this 40-kg dog would "see" in a normal physiologic state approximately 1460 mg of prednisone (or prednisolone) per year.

From these calculations I have developed what I called my "safe annual steroid dose" formula:

$$\text{Body weight (BW)(kg)} \times 30 = \text{milligrams of prednisone per year}$$

$$\text{or BW (lb)} \times 15 = \text{milligrams of prednisone per year}$$

365 Days times 0.4 equals 36.5; but, for the sake of ease of mathematics and to be even safer, I have chosen to use the number 30. This number (30) is based on a combination of several publications reporting the side effects of GCs as related to dose and on over 10 years of using this formula in my own practice and arriving at the safe use.

Again considering the 40-kg dog, I would calculate: $40 \times 30 = 1200\text{ mg}$ of prednisone to be the "safe annual steroid dose". This value is less than the range of that considered physiologic for that dog (1460 mg).

If this dog required more than what I believed to be the "safe annual dose" of prednisone or prednisolone to control its dermatologic disease (i.e., pruritus from allergies or atopic dermatitis), I would either add a second medication in an effort to decrease the amount of GC needed or change medications (i.e., to cyclosporine). Steroid treatment protocols generally begin with higher doses and then are tapered, but again looking at these calculations in this way can be a helpful guide.

If the dog needs more than the "safe annual steroid dose" and the owner declines further diagnostic workup or other therapy, I recommend monitoring for weight gain and urinary tract infection since these are the most prevalent side effects with ongoing GC therapy. First, I would discuss in detail my recommendations for feeding and have the dog weighed regularly to monitor for weight gain. I would also perform a cystocentesis for urinalysis and urine culture and sensitivity test. It is critical that the urine in dogs receiving steroid therapy be cultured to identify an infection. Dilution of the urine and the antiinflammatory effects of the steroids reduce the likelihood of identifying bacteruria or inflammatory changes suggestive

of infection in the routine urinalysis. Although the urine specific gravity would be expected to be low (about 1.012), if there were protein or glucose in the dilute urine, a serum chemistry to assess for any early renal disease or diabetes would be indicated. I would expect the alkaline phosphatase and alanine aminotransferase to be elevated and for the complete blood count to reveal a stress leukogram.

In summary, the rational use of GCs in veterinary dermatology requires the clinician to be familiar with the pharmacologic, physiologic, and side effects of steroids as a class and the individual formulations used in their practice. GC use should be limited and kept to a minimum by using adjunctive therapies (e.g., antibiotics, antihistamines, fatty acids, topical therapies) whenever possible. A diagnosis should be made before determining the therapeutic regimen, and long-term therapy should be monitored with frequent examinations and laboratory testing as indicated.

CHAPTER 90

Feline Pruritus Therapy

SOPHIE GILBERT, *New York, New York*

INTRODUCTION

To maximize treating a pruritic cat, it is important to address the underlying cause. A complete signalment and history, along with a thorough physical examination and diagnostic procedures are required. Once the underlying cause is known, a specific treatment can be instituted. At his time, or during the diagnostic workup, some cats will require a short-term symptomatic treatment to increase their quality of life, as well as that of their owners. Because most underlying pruritic diseases in cats cannot be cured, most affected cats require a combination of specific and symptomatic therapy to control the condition and to provide them with a comfortable life.

SPECIFIC TREATMENTS

Once the underlying cause has been diagnosed, it may be possible to address the cause of the pruritus by giving a

specific treatment. Many of these are discussed elsewhere in this section. Some examples of specific therapies are summarized below.

- Parasitic dermatitis (notoedric acariasis, otodectic acariasis, cheyletiellosis, pediculosis, trombiculiasis, and demodicosis): lime sulfur dips, selamectin, ivermectin, fipronil spray; treat all in contact animals (see Chapter 98)
- Dermatophytosis: topical and parenteral antifungal products; treat all in contact animals, as well as in the environment (see Chapter 105)
- Pyoderma/*Malassezia* dermatitis: appropriate oral antibiotic for 3 to 4 weeks for pyoderma and oral antifungal product for *malassezia* dermatitis (see following paragraph)
- Flea allergy dermatitis: strict flea control, which includes treating the cat with adulticidal and larvicidal products and treating the environment

- Food allergy: restrictive diet that does not include the offending food stuff (see Chapter 87 and Section V on Evolve).
- Atopic dermatitis (AT): avoidance of the offending allergens and allergen-specific immunotherapy (ASIT) (see discussion later in the chapter and in Chapter 92)
- Psychogenic alopecia: correction of the triggering factor with or without administration of behavior modification drugs (see discussion later in the chapter)

Treating the Secondary Infections (Pyoderma and *Malassezia* Dermatitis)

When evidence of pyoderma and/or *malassezia* dermatitis is evident from the cytologic examination, these should be treated because as infection may contribute considerably to the pruritus and in rare cases may be the only cause of the pruritus. Antibiotic or antifungal therapy may be given as sole therapy for 3 to 4 weeks to assess their efficacy. When a pyoderma is present, culture and antibiotic sensitivity may be recommended. However, because cytologic examination often reveals the presence of cocci, in many cases, empiric antibiotic therapy is usually tried first. Antibiotics that have been used successfully to treat pyoderma in cats include clavulanic acid/amoxicillin (15 mg/kg q12h orally [PO]), cefadroxil (22 mg/kg q12h PO), marbofloxacin (Zeniquin, Bayer, 3 to 5 mg/kg q24h PO), lincomycin (20 mg/kg q12h PO), and clindamycin (5.5 mg/kg q12h or 11 mg/kg q12h to 24h PO). Vomiting and diarrhea are common side effects of most of these drugs.

Malassezia dermatitis can be treated with oral itraconazole (Sporanox, Janssen Pharmaceutica, 5 mg/kg q24h PO). Intermittent ongoing therapy may be necessary to control recurrent infections. Terbinafine (Lamisil, Novartis) has been used successfully to treat secondary *malassezia* dermatitis in allergic dogs at a dosage of 30 mg/kg once daily (Rosales et al., 2005). Therefore terbinafine may also be considered as a treatment option for cats with *malassezia* dermatitis.

Treating Feline Atopic Dermatitis

The diagnosis of AD in the cat is based primarily on the history and clinical signs and by ruling out other pruritic diseases. It is important to explain to the owner that AD is not curable but only manageable and that both specific and symptomatic treatments will likely be required for life. Combining treatments helps to optimize the chance of controlling the pruritus in these patients. Specific treatments of AD include avoiding the offending allergen and allergen-specific immunotherapy or ASIT. These treatments require identification of the environmental allergens involved in the disease, which may be done by performing intradermal testing (IDT) and/or allergen-specific IgE serology (for more details, see *Kirk's Current Veterinary Therapy XIII*, p 564). Because nonrelevant positive reactions can be seen with both tests, special care should be taken when interpreting them and selecting the allergens to be included in the ASIT.

Although considered the gold standard, IDT is more difficult to perform and interpret in the cat than in the dog because of the thinner skin of the cat. This

makes performing intradermal injections more difficult. Furthermore, positive tests in cats may be characterized by the formation of softer, nonerythematous wheals or by wheals that are very subtle and disappear rapidly when compared to dogs. Weak reactions also may be caused by the use of suboptimal allergen concentrations. Indeed, recently it was shown that allergen concentrations used in cats should be revised since most appear too low (Austel et al., 2006).

Allergen-specific IgE serology offers an alternative to IDT. Because of the difficulty of performing and interpreting IDT in the cat and because the benefits of successful ASIT may be comparable to those of IDT (Halliwell, 1997), many dermatologists prefer this test over IDT in this cats. Greer Laboratories (www.greerlabs.com), Heska Corporation (Allercept, www.heska.com), and VARL (Veterinary Allergy Reference Laboratory, www.varallergy.com) offer allergen-specific IgE serology in cats in the United States.

Limiting contact with the offending allergen is often impossible or impractical, but avoidance may be possible with some allergens, including wool, kapok, tobacco, and feathers. It is also possible to decrease the level of dust mites in the environment (see Chapter 94); and although difficult, it may be possible to limit exposure to pollens.

ASIT is the treatment of choice for dogs with AD when it is not possible to avoid the offending allergen. Double-blinded, placebo-controlled studies demonstrating the efficacy of ASIT are still lacking in the cat. However, open studies have shown success rates that vary from 45% to 100% (O'Dair and Foster, 1995; Scott, Walton, and Slater, 1986). Accordingly, ASIT may represent the most appropriate long-term control method for a cat with nonseasonal AD. The success of ASIT depends on the accuracy of the diagnosis, the formulation of the vaccine (selection of the allergens), and the realization that each program must be tailored to the specific needs of the patient, relative to frequency of injections and number of allergens used. In addition, ASIT requires compliant owners and cooperative patients.

The recommended induction protocol of ASIT is the same in the cat as in the dog; however, the protocol may be varied, and I prefer to use a lower maintenance dosage of 0.5 ml every 1 to 2 weeks (rather than the canine protocol of 1 ml every 10 days to 3 weeks). Again, intervals between injections may be decreased or increased according to the response obtained, and the dose may be decreased to reduce the severity of potential side effects such as increase in pruritus. In addition, it may be helpful to premedicate the cat with an antihistamine before giving the injection. Some cats with severe pruritus may also require the administration of oral symptomatic therapy during the induction phase of ASIT while waiting for the benefits of ASIT to become clinically apparent (see following paragraphs). If improvement is not evident after 1 year, ASIT is considered a failure and should be discontinued. However, if improvement is noted, injections should be given for life. It is important to give positive reinforcement to the client such as handouts, phone communications, and rechecks to continue what can be a difficult task for some.

SYMPTOMATIC TREATMENTS FOR PRURITUS

It is important to make a point of understanding each client's tolerance for his or her cat's level of pruritus. The choice of symptomatic therapy may differ, depending on whether it will be used for short-term or long-term administration.

Concomitant short-term symptomatic therapy may be required during the time of the diagnostic procedures or during the induction phase of ASIT if the cat is severely pruritic and uncomfortable. In this case fast and satisfactory relief is required; therefore corticosteroids are often chosen over other antipruritic drugs. It is important to remember that symptomatic therapy is likely to interfere with the diagnostic procedures and may delay IDT. Therefore, to assess the effect of a treatment trial such as flea control, ectoparasite therapy, or elimination diet, the oral corticosteroid therapy should be discontinued, and the cat should be monitored closely for recurrence of the pruritus and clinical signs. In addition, to rule out food allergy, the elimination diet trial must be followed by challenging the cat with its original diet.

When long-term therapy is required, nonsteroidal therapy should be tried first because it may be successful and carries fewer potential side effects than corticosteroids. Although the success rate is much lower than with corticosteroids, I generally prescribe chlorpheniramine in conjunction with essential fatty acids (EFAs). Nonsteroidal therapy is also recommended in cats in which corticosteroids are contraindicated. However, some pruritic diseases or reaction patterns do not respond to nonsteroidal therapy, and many cats are still given corticosteroids as a long-term therapy.

Medicating may be a problem in some cats, and owners should be counseled about the techniques and "tricks" useful for oral treatment of cats. Administration of drugs may be limited to only once daily in difficult cats. If an elimination diet trial is not ongoing, tuna juice, butter, and petroleum jelly may be used to hide the medication; or the drug may be compounded with flavor added. Some drugs such as corticosteroids (methylprednisolone acetate [Depo Medrol, Pfizer]) may also be administered parenterally rather than orally.

Corticosteroid Therapy

Corticosteroids are the most consistently effective drugs in the management of pruritus in cats. Because corticosteroids usually provide fast and satisfactory relief, they represent a better option for short-term antipruritic therapy than nonsteroidal agents that have a lower success rate. Moreover, despite all diagnostic and therapeutic efforts, some cats may respond only to corticosteroid therapy. However, use of corticosteroids implies a compatible differential diagnosis, and they should not be administered to cats with suspicion of infectious diseases such as dermatophytosis, immunosuppressive viral infection, latent toxoplasmosis, or other bacterial or viral diseases. A number of systemic or organ-system based diseases can also constitute relative contraindications for corticosteroids, particularly repositol compounds. These include diabetes

mellitus, pancreatitis, kidney failure, cardiomyopathy, and some liver diseases.

Oral short-acting corticosteroids are preferred over injectable long-acting (repositol) corticosteroids since they can be discontinued any time, which enables the efficacy of the treatment trial to be assessed or development of adverse effects to be limited. However, repositol corticosteroids may be used in cats unable to swallow pills or difficult to treat (e.g., aggressive cats, outside cats). Because prednisone must be converted into active prednisolone in the liver and cats may be deficient in this capacity, prednisolone is preferred over prednisone in this species (Graham-Mize and Rosser, 2005).

Cats may be relatively resistant to corticosteroids in comparison to dogs because of the rate of the metabolism of the corticosteroids, a difference in the extent of oral absorption, or a difference in the number and affinity of corticosteroid receptors in the skin and the liver (van den Broek and Stafford, 1992). Although cats tolerate corticosteroids fairly well, side effects may be seen, especially with long-term therapy. The possibility of developing diabetes mellitus is a serious concern in cats receiving long-term corticosteroid therapy. Iatrogenic hyperadrenocorticism, although rare in cats, may also occur.

When oral corticosteroids are used long term, tapering doses should be given according to the response observed. The initial dose is usually higher than in dogs and is given daily until remission is obtained (usually 1 week to 10 days). The dosage is gradually reduced to the lowest alternate-day schedule that controls the symptoms. Suggested corticosteroids and dosing schedules follow:

- *Prednisolone* or *methylprednisolone* 1 to 2 mg/kg q24h PO for 1 to 2 weeks; then switch to alternate-day basis at lowest possible dose
- *Dexamethasone* 0.1 to 0.2 mg/kg or 0.25 to 1 mg/cat q24h PO for 1 week; then gradually increase the interval between therapy to one to three times a week
- *Triamcinolone* 0.2 to 0.4 mg/kg q24h PO for 1 week; then gradually increase the interval between therapy from every week to every three weeks.
- *Methylprednisolone acetate injectable*, 4 mg/kg or 20 mg/cat intramuscularly. Cats should not receive more than four injections a year (and no more often than once, every 3 months). However, some cats with severe lesions of the eosinophilic disease complex may initially require up to three injections 2 weeks apart before showing a response.

When giving corticosteroid therapy, I usually start with prednisolone at the dosage of 1 mg/kg once daily and have found this dose to be generally successful in controlling the pruritus of atopic cats. Lesions of the eosinophilic disease complex such as eosinophilic granuloma and indolent ulcer may be more difficult to control and often require higher doses or more potent corticosteroids. If the expected result is not obtained or if the cat is showing undesirable effects (e.g., polyphagia, polyuria-polydipsia) with one type of corticosteroids, another type may be tried. Antihistamines and EFAs may potentiate the effects of corticosteroids, facilitating a decreased dose of corticosteroids. Tachyphylaxis may

occur with long-term corticosteroid therapy. Some cats may require the use of oral corticosteroids only when they have a pruritic outbreak.

NONSTEROIDAL THERAPIES

Essential Fatty Acids

EFA supplements containing ω -3/ ω -6 fatty acids are potent modulators of prostaglandin and leukotriene synthesis. These supplements have been shown to be effective in some pruritic cats. Formulations containing ω -3/ ω -6 have been reported to be of help and to give positive response in 40% to 75% of cats with inflammatory skin disease (Miller, Scott, and Wellington, 1993; Harvey, 1993). However, I have not been able to reduce the pruritus level in cats with the administration of EFA as the only treatment. Because these studies did not take into consideration the EFA content of the diet and therefore the type of fatty acids, the ω -6/ ω -3 ratio (5:1 to 10:1) and the dose of each fatty acid necessary to provide a maximum of efficacy are still unknown.

Many formulations composed of either ω -3 or combination of ω -6 and ω -3 at varying ratios can be found. Liquid formulation, capsule, or chewable tablets can be purchased (3V Caps, IVX Animal Health; Dermcaps, IVX Animal Health; Efavet, Efamol; Vetriderm, Bayer; Actis Omega, Sogeval). EFAs should not be administered during an elimination diet trial, and cats having allergy to fish should not be given fish oil.

EFAs should be given for at least 6 weeks to be able to assess their efficacy, and, if improvement is noted, they should be given for life. It is recommended to give the EFAs in combination with antihistamines for synergistic effects and as a supplement to long-term corticosteroid therapy for their sparing effect on the corticosteroids. Even when ineffective for decreasing pruritus, EFAs increase the skin and hair coat quality considerably. Adverse effects are uncommon but include vomiting, diarrhea, and weight gain.

Antihistamines

Antihistamines are most likely to be effective when the skin is minimally inflamed and therefore efficacy is likely to be increased after treating the complicating factors, underlying causes, and controlling inflammation with a short course of corticosteroid therapy. Conversely, antihistamines are believed to work best if given before histamine release and therefore should be administered without interruption in cats with chronic pruritus.

Chlorpheniramine was reported to be very effective in atopic cats, with improvement in 73% of cases (Miller and Scott, 1990). Chlorpheniramine (2 to 4 mg/cat q12h PO) is my recommended antihistamine in cats because it is often the most effective and is usually well tolerated. The 4-mg tablet makes it convenient to administer, although, once broken, it may have a bitter taste. Alternatively clemastine (0.67 mg/cat q12h PO) can also be used and was shown to give positive results in 50% of cases (Miller and Scott, 1994). Other antihistamines that have been used in cats with variable success are diphenhydramine 0.5 mg/kg q12h PO, cyproheptadine 2 mg/cat q12h PO,

hydroxyzine 1 to 2 mg/kg q12h PO, and oxatomide 10 to 30 mg/cat q12h PO.

Because response to antihistamines is notoriously individualized and unpredictable, an antihistamine trial with several antihistamines may be performed. Each antihistamine is given to the cat for 2 weeks to assess its effect and elicit which has the greatest efficacy. There may be a synergistic effect between the EFAs and antihistamines, and, like EFAs, antihistamines may also potentiate the effect of the corticosteroids. Adverse effects include lethargy, diarrhea, polyphagia, polyuria/polydipsia, and behavioral changes (vocalization). Some cats may experience hyperexcitability. Antihistamines must be used with caution in the presence of liver disease, glaucoma, urinary retention, gastrointestinal atony, seizures, and pregnancy.

Behavior Modification Drugs

Behavior modification drugs are mostly recommended in cats with behavior disorders but may also be helpful in cats in which excessive grooming is their primary clinical presentation. Their efficacy is the result of their specific effect on anxiety and stereotypic behavior and the antihistaminic properties that some of these agents have.

Clomipramine (Clomicalm, Novartis, 2 to 5 mg/cat q24h PO) and amitriptyline (5 mg/cat q12h to q24h PO) are tricyclic antidepressants. Tricyclic antidepressants exert their primary clinical effects by inhibiting the presynaptic reuptake of serotonin and norepinephrine. In addition, they have the ability to block H_1 and H_2 receptors. Adverse effects include sedation; increase in appetite; weight gain; and anticholinergic effects such as dry mouth, urine retention, and reduced tear production. Tricyclic antidepressants may be contraindicated in cats with heart or hepatic disease and history of urinary retention and in epileptic patients. Clomipramine comes in 20-mg tablets and has a bitter taste. For convenience, it may be compounded in 2- to 5-mg tablets with flavor added.

Fluoxetine (Prozac, Lilly, 1 to 5 mg/cat q24h PO) is a selective serotonin reuptake inhibitor (SSRI). Because of their specificity, SSRIs do not affect histamine or acetylcholine; however, they can still cause anorexia, irritability, nervousness, anxiety, sleep disturbance, and changes in elimination patterns.

Behavior modification drugs should be administered for a minimum of 4 weeks before evaluating the clinical response. They should not be discontinued abruptly but should be slowly tapered over a period of 3 weeks (clomipramine and amitriptyline) to 6 weeks (fluoxetine). Tricyclic antidepressants and SSRIs should not be used together or concurrently with monoamine oxidase inhibitors (MAOIs) (i.e., amitraz, selegiline) because MAOIs enhance their toxicity and can lead to the serotonin syndrome. Serotonin syndrome is characterized by a hyper-serotonergic state resulting from elevations of central nervous system serotonin, which may reach potentially fatal levels. It usually occurs when drugs with different mechanisms of action are mixed together. Clinical signs may include agitation, drowsiness, myoclonus, hyperreflexia, tremor, hyperthermia, diarrhea, coma and death.

Cyclosporine

Cyclosporine is a calcineurin inhibitor with potent immunomodulatory activity. It is used in dogs with AD with success rates similar to those of corticosteroids (see Chapters 55 and 84). Because side effects that are reported with corticosteroids are not observed with cyclosporine, this drug represents a good option in atopic cats in which corticosteroids are contraindicated, when the dose of corticosteroids cannot be tapered to an acceptable dose, and when nonsteroidal therapy has failed. Infectious diseases, if present, should be cleared before starting cyclosporine therapy. Theoretically, cyclosporine may be used before IDT and at the beginning of ASIT since, unlike corticosteroids, it is believed not to interact with the results of the test and the therapy. However, this notion has been challenged by a recent study. Brazis and colleagues (2006) did show a significant inhibition of cutaneous histamine release and wheal formation following intradermal challenge in dogs sensitized to *Ascaris suum* that were treated with cyclosporine. The dogs were given 5 mg/kg of cyclosporine orally for 4 weeks. Inhibition of histamine release and wheal formation was already significant after 2 weeks of treatment. Based on these results, administration of cyclosporine may not be recommended before IDT in cats since IDT reactions in this species are already often weak and subtle.

In cats cyclosporine has been used with encouraging results to treat eosinophilic disease complex lesions, facial/neck pruritus, self-induced symmetric alopecia, plasmacytic stomatitis, and urticaria pigmentosa. The recommended dosage ranges from 5 to 8 mg/kg q24h orally. Lesions of eosinophilic disease complex may require higher dosages (up to 12.5 mg/kg q24h). It may be possible to start alternate-day regimen after 4 to 6 weeks if sufficient improvement of the clinical signs is seen. The lesions may stay in remission or be controlled with twice-weekly administrations in some cats. Corticosteroids may be given in conjunction with cyclosporine to provide a faster/better control of the lesion. Then corticosteroids are discontinued and cyclosporine is continued alone.

Cyclosporine is available in microemulsion designed to increase the drug intestinal absorption and bioavailability (Atopica, Neoral, Novartis). The possibility of food affecting the bioavailability of cyclosporine has not been studied in the cat; therefore it is unknown if the drug should be given on an empty stomach rather than with food. Oral solution and 10- and 25-mg capsules can be purchased for convenience in cats. The drug may be compounded with flavor added to increase compliance in difficult cats not receiving an elimination diet trial. My colleagues and I have used the injectable form of cyclosporine (Sandimmune) in some difficult cats that could not be given pills, with apparently similar success as when given orally. The initial dose used varied from 2.5 to 5 mg/kg daily subcutaneously, and it was possible to increase the interval between injections to once or twice weekly in some cats. Overall the injections were well tolerated, and adverse reactions were not observed.

The most common side effects reported in cats include anorexia, vomiting, and diarrhea, which usually resolve spontaneously or after discontinuing the medication for

a few days. When vomiting is persistent, the administration of metoclopramide (2.5 mg/cat PO 30 minutes before administration of the cyclosporine two to three times a day) may help. Less common adverse effects are gingival hyperplasia, hypertrichosis, and modification in behavior.

Although cyclosporine appears to be a safe medication, it is only recently that this drug is being used as long-term therapy. Therefore long-term safety is still unknown, and cyclosporine must be used with caution. It may be wise to recommend monitoring the cat by performing semianual complete blood count, chemistry panel, and urinalysis. Feline immunodeficiency virus and feline leukemia virus serology are recommended before starting cyclosporine therapy. Because fulminant and fatal newly acquired acute toxoplasmosis has occasionally been reported in cats (Last et al., 2004), a serologic test for toxoplasmosis is also recommended. The interpretation of the serology is still uncertain; however, it may be prudent to recommend that seronegative cats not be fed raw meat, poultry viscera, or bones and not be allowed to hunt and scavenge during cyclosporine therapy because they may be at risk for developing the disease. Seropositive cats may also be at risk for developing the disease. Nevertheless, and although not known, it is unlikely that reactivation would occur with the dose used to treat atopic cats (much lower than the dose given for renal transplant). Human patients who developed cutaneous lymphoma while being treated with cyclosporine therapy raised some concerns in animals. So far there are only anecdotal cases of dogs developing neoplasia, and this has not been reported in cats.

Adjunctive Therapy

Topical Therapy

Giving a bath to a cat may be a real challenge, and topical antipruritic therapy with cream and gel has little value because of licking and self-grooming. However, some antipruritic lotion and pump spray products containing hydrocortisone, triamcinolone, lidocaine, diphenhydramine, or pramoxine may be helpful as adjunctive therapy in cases of localized pruritus. Potent topical corticosteroids such as triamcinolone (Genesis Spray, Virbac), should be used with special care in cats because of their thin skin and the potential risk of inducing skin fragility.

I have used tacrolimus ointment (Protopic 0.1%, Astellas) in atopic cats with eosinophilic plaques or focal pruritus. Tacrolimus is a macrolide immunosuppressant that belongs to the same family as cyclosporine (see Chapter 55), but it is for topical dermatologic use only. A thin film of the ointment is applied to the lesion once or twice daily until resolution or significant improvement of the lesion and then as needed. The cat should wear an Elizabethan collar following application to prevent licking of the drug and systemic absorption. Secondary infections should be treated before starting tacrolimus therapy. Rare cases of malignancy (such as lymphoma) have been reported in humans treated with tacrolimus ointment. Therefore, even though a causal relationship has not been established in these patients, owners should wear gloves when using this ointment. Cases of malignancy have not been reported in dogs and cats; however, caution should be exercised.

Flea Control

Because of the high frequency of flea allergy dermatitis, any pruritic cats living in an area where fleas are seen should receive strict flea control. In addition, like dogs, cats with AD may also be predisposed to develop flea allergy dermatitis or flea bites may exacerbate the AD.

Elizabethan Collar, Bandannas/Neck Wraps, and Soft-Paws

An Elizabethan collar can be used to limit self-trauma during the initiation of the symptomatic treatment. The collar may also reduce licking of topical treatment, therefore reducing any systemic absorption of the drug or decreasing drug efficacy. Clear plastic or soft foamlike collars are preferred. Bandannas and neck wraps can prevent self-mutilation in the neck areas in cases of neck pruritus or idiopathic ulcerative dermatosis. Soft-paws (SmartPractice) are soft plastic covers that are glued onto the nail. They are marketed as an alternative to declawing but may be also useful in preventing self-induced trauma.

CHAPTER 91

Shampoo Therapy

WAYNE S. ROSENKRANTZ, *Tustin, California*

INTRODUCTION TO SHAMPOO THERAPY

The use of topical therapeutics and in particular shampoo therapy has gained increasing popularity in veterinary dermatology. Shampoos are one of the easiest and most complete vehicles to use when applying topical therapeutics, and shampoo therapy can be highly beneficial in the management of many different types of skin disorders (Guaguere, 1996; Kwochka, 1993). This is particularly the case in allergic, seborrheic, and infectious diseases. In many patients shampoo therapy can be used as a sole

treatment or as an adjunctive therapy that allows reduced dosages or reliance on systemic therapy (Scott et al., 2001). Owner compliance can sometimes be a problem with this type of therapy, as it can be difficult and time-consuming. However, it does allow many owners to actively participate in the management of their pets' skin condition.

Gaining familiarity with the shampoo products that are commercially available is very important. Many products are not closely regulated regarding their active ingredients or formulations; thus first-hand experience is necessary. By using the shampoos on his or her own

pets and patients, the veterinarian can gain experience regarding the potency, efficacy, and safety of a product and be knowledgeable about recommending these products to clients for their pet's skin conditions. The recommended frequency of shampooing varies with the underlying condition. However, in most chronic skin diseases weekly shampooing with the proper product can be very helpful. Some products require adequate contact time for the best efficacy, but it is critical that complete rinsing be emphasized to avoid or reduce irritancy. In general cool water is recommended, especially in cases with allergic skin disease.

SHAMPOOS FOR ALLERGIC SKIN DISEASES

Topical therapy is extremely important in the management of allergic skin diseases. Many new products are available that contain better delivery systems and active ingredients that help to control pruritus and moisturize the skin. The use of these shampoos allows for reduced systemic absorption and increased activity. The main advantages are control of pruritus by removing allergens from the skin surface and having direct antipruritic effects. For this form of therapy to be most effective, frequent shampooing is often necessary; this may vary from case to case, but generally once to twice a week and occasionally more frequently. When combined with systemic therapy, even weekly bathing can have a synergistic effect.

Water is often overlooked as a therapeutic agent. It aids in hydrating and cooling the skin and can help remove crusts and soften and clean the skin. Water combined with a shampoo can be particularly effective. When combined with proper emollients and moisturizing agents it can help retain the moisture in the skin after hydration during bathing. On the other hand, if used repeatedly without proper emollients and moisturizing agents, water can dry out the skin by removing the skin's natural barriers that prevent xerosis.

Many different specific antipruritic and moisturizing agents can be incorporated into shampoos (Table 91-1). Because shampoos are not left on indefinitely and are

rinsed off after a period of time, some active ingredients are not as effective or practical to use in shampoo delivery systems. Many companies offer leave-on rinses or sprays that contain the same active ingredients that can be used after or in-between shampooing to prolong their beneficial effects. Such rinses and sprays are more commonly incorporated into products used for allergy management but can also be found for other conditions. Short-term relief from pruritus can be achieved by using shampoos with specific antipruritics. The mechanism of action varies among different products. Some inactivate pruritic mediators (glucocorticoids and antihistamines); others act as topical anesthetics (pramoxine, benzoyl peroxide, and tars); still others function by moisturizing the skin. Moisturizing agents include oils (safflower, sesame, lanolin) and hygroscopic agents (propylene glycol, glycerin, colloidal oatmeal, urea, and lactic acid). Since there are so many products available on the market, it is important that the practitioner become familiar with specific products that contain these active ingredients to be able to make proper selections for specific cases.

One of the antipruritic topical agents that I use most commonly is the topical anesthetic pramoxine hydrochloride. It is available in a few commercial products (see Table 91-1). The duration of action is short and becomes even shorter when used frequently and repetitively. Pramoxine is used primarily in combination with colloidal oatmeal. Diphenhydramine is an antihistamine available for topical use and available in veterinary formulations: Histacalm, Resihist, and Histacalm spray (2% diphenhydramine) (Virbac). Topical antihistamines have limited value in controlling pruritus in veterinary dermatology, but an occasional case exhibits some benefits.

Other popular products that are useful in the management of allergic skin disease are moisturizing and hypoallergenic shampoos. Many times these products are followed with the same active agent as a leave-on spray or rinse. My favorites are Hy-Lyt-EFA and Relief (DVM Pharmaceuticals); Allermyl, Allergroom, and Epi-Soothe (Virbac); and Dermal Soothe Hydra-Pearls cream rinse (Vetoquinol). Allermyl shampoo (Virbac) is a relatively

Table 91-1

Antipruritic and Moisturizing Products

Products	Ingredients	Formulation	Manufacturer
Allergroom	Moisturizing	Shampoo	Virbac
Allermyl	Moisturizing	Shampoo/rinse	Virbac
Hy-Lyt-EFA	Moisturizing	Shampoo/rinse	DVM Pharmaceuticals
Hydra Pearls	Moisturizing	Shampoo/rinse	Vétoquinol
DermaHypoCS	Moisturizing	Shampoo	DermaPet
EpiSoothe	Colloidal oatmeal	Shampoo	Virbac
Allay oatmeal	Colloidal oatmeal	Shampoo	DermaPet
Resisoothe	Colloidal oatmeal	Rinse	Virbac
Relief	1% Pramoxine	Shampoo/rinse	DVM Pharmaceuticals
Resiprox	1.5% Pramoxine	Rinse	Virbac
Histacalm	Diphenhydramine	Shampoo/rinse	Virbac
Fluocinolone acetonide	Triamcinolone 0.01%	Shampoo	Hill
Cortisoothe	Hydrocortisone 1%	Shampoo	Virbac
Douxo	Phytosphingosine	Shampoo/spray spot-on	Sogeval

new shampoo for atopic dermatitis and contains linoleic acid, vitamin E, and L-rhamnose in a microemulsion. L-rhamnose has been shown to inhibit some proinflammatory cytokines *in vitro*, and the formulation is meant to restore the barrier function of the stratum corneum, which may be impaired in atopic dermatitis. In a 3-week clinical trial greater than 50% improvement in pruritus in 35 dogs with atopic dermatitis was seen when shampooing with Allermyl and topical application of Allermyl rinse every 3 days (Reme et al., 2004).

A new group of products containing phytosphingosine (PS) has just been released (Douxo, Sogeval) that has been used primarily for seborrheic conditions; however, the active agent also has moisturizing and antiinflammatory properties and may be of value for allergic skin disease management as well. PS is a key molecule in the natural defense mechanism of the skin. It is a component of ceramides, 40% to 50% of the main lipids responsible for maintaining the cohesion of the stratum corneum and correct moisture balance of the skin. PS has antiinterleukin-1 activity, which impairs the production of prostaglandin E_2 and inhibits kinase protein C. This may be one of the mechanisms by which it may help with allergic skin disease management.

Another new area of interest is using topical therapy as a denaturing agent to inactivate percutaneous allergens before they can create disease. This has been recommended mostly for control of house dust mite allergens, which is the most common environmental allergen involved with canine atopic disease (see Chapter 94). The allergen denaturing agent is incorporated in a shampoo base (Allerage, Aveho Biosciences) and may help to control pruritus by lowering allergen levels on the skin. I and others have anecdotal reports of help with Allerage (shampoo and spray formulations) as a topical therapy in canine atopic dermatitis.

Shampoos with glucocorticoids can be tried for more generalized allergic conditions but often have no residual effects because they are rinsed off of the skin. One common product incorporates hydrocortisone (Cortisooth, Virbac) and has no known detectable systemic absorption

or side effects. A more potent fluorinated glucocorticoid shampoo is available (Fluocinolone acetonide, Hill) but is expensive. It carries minimal concerns regarding systemic absorption and side effects and appears safe to use as long as it is adequately rinsed off the skin.

SHAMPOOS FOR SEBORRHEIC DISORDERS

Antiseborrheic shampoos function by normalizing epithelialization or removing surface scale. A keratoplastic effect is optimal for an antiseborrheic shampoo to be effective. This is where the rate of division of the basal cells is reduced or "normalized". Most antiseborrheic shampoos also have a keratolytic effect, in which there is an elimination of excess corneal layers by increasing desquamation. This is thought to be caused by a softening and a reduction of the intercellular connection of the corneocytes, resulting in increased desquamation of the stratum corneum. Many keratoplastic and keratolytic agents are commercially available in shampoo formulations (Table 91-2). Also, many of the previously listed moisturizing shampoos that are used for allergic skin disease management can be used in mild, dryer forms of scaly skin disorders. These function primarily by increasing the moisture content of the skin; many products also have emollient effects.

Salicylic Acid and Sulfur Shampoos

Salicylic acid is a keratolytic agent. It causes a reduction in skin pH, which leads to an increase in the amount of water that the keratin of the stratum corneum is able to absorb. In the desquamation process it has a direct effect on intercellular cement and intercellular junction system (desmosomes). These actions help soften the corneal layer. Salicylic acid acts synergistically with sulfur and these two compounds are often present in equal quantities in shampoos. Its efficacy varies with concentration. Sulfur is mildly keratolytic. It forms hydrogen sulfide in the corneal layer and has numerous other antiseborrheic properties. The keratoplastic action is explained by a direct cytostatic effect and possibly because it interacts

Table 91-2

Antiseborrheic Shampoos

Product	Ingredients/Uses (Active Ingredients)	Formulation	Manufacturer
SebaLyt/SeboRx	Sulfur 2%/2%, salicylic acid 3%/2%, triclosan 0.5/0.5%	Shampoo	DVM Pharmaceuticals
Sebolux	Sulfur 2%, Na-salicylate 2.3%	Shampoo	Virbac
SebaMoist/ SebaHex	Sulfur 2%, salicylic acid 2%/chlorhexidine 2%	Shampoo	Vétoquinol
DermaSebS	Benzoyl peroxide 2.5%, sulfur 2%, salicylic acid 2%,	Shampoo	Dermapet
NuSal-T	Coal tar 2%, salicylic acid 3%, menthol 1%	Shampoo	DVM Pharmaceuticals
T-Lux	Coal tar 4%, sulfur 2%, Na-salicylate 2.3%	Shampoo	Virbac
LyTar	Juniper tar 3%, sulfur 2%, salicylic acid 2%	Shampoo	DVM Pharmaceuticals
Allerseb-T	Coal tar 4%, sulfur 2%, salicylic acid 2%	Shampoo	Virbac
Sulf OxyDex	Benzoyl peroxide 2.5%, sulfur 2%	Shampoo	DVM Pharmaceuticals
Selsun Blue	Selenium sulfide 1%	Shampoo	Ross
Keratolux	Salicylic acid 1%, zinc gluconate 0.5%, pyroxidine 0.5%	Shampoo	Virbac
Etiderm	Ethyl lactate 10%	Shampoo	Virbac
Douxo	Phytosphingosine	Shampoo/spray/spot-on	Sogeval

with epidermal cysteine to form cystine, an important component of the corneal layer. It is also antiseptic. Sulfur can be very drying, however, and it also can carry an odor, depending on the formulation. It exerts synergistic activity with salicylic acid most effectively when both substances are incorporated into the shampoo in equal concentrations. My favorite combination salicylic acid and sulfur products are: Sebolux (Virbac), Sebalyt and SeboRx (DVM Pharmaceuticals), and SebaMoist and SebaHex (Vetoquinol), and DermaSebS Shampoo (Derm-apat). Sulfur and salicylic acid shampoos work best for light scaling and flaking keratinization defects.

Tar Shampoos

Tar is a keratoplastic agent. It reduces nuclear synthesis in the epidermal basal layers and creates antiseptic and antipruritic effects. There are many different sources and varieties of this active agent. Skin drying, discoloration of light-colored coats, and irritation can be seen with tar-based products but are more common when the concentration is above 3%. There is also some concern about coal tar-based products being carcinogenic; some products containing coal tar have a labeling warning about this concern. Tar shampoos are *contraindicated in the cat* because of a much higher degree of irritancy; in some cases they make cats systemically ill. Because of the increased effectiveness of other nontar products, I rarely use tar-based products. If necessary in more severe forms of seborrhea, particularly in some variants of idiopathic cocker seborrhea or severe forms of sebaceous adenitis, I use solubilized tar (T-lux [Virbac]), 2% tar and salicylic acid (NuSal-T [DVM Pharmaceuticals]), or even more potent tars (Lytar, [DVM Pharmaceuticals] and Allerseb-T [Virbac]). Because of their potency and potential side effects, it is critical to make sure that all tar shampoos are completely rinsed off the skin.

Selenium Disulfide Shampoos

Selenium disulfide is keratolytic and keratoplastic by reducing epidermal turnover and impairing disulfide bridge formation in keratin. It is also antiseborrheic but can have irritant and drying effects. It is contraindicated in the cat for the same reasons listed for tars. I rarely use this shampoo; but on occasion it can be of value in very greasy, oily keratinization defects with concurrent yeast dermatitis in which client finances are a concern because it is less expensive and available over the counter.

Benzoyl Peroxide Shampoos

Benzoyl peroxide is often thought of as being antibacterial, but it is also antiseborrheic by hydrolyzing sebum and reducing sebaceous gland activity. Benzoyl peroxide exerts a follicular flushing action, which is very useful when treating comedone disorders and/or follicular hyperkeratosis. Irritant side effects have been reported, especially in concentrations above 5%. The skin may become dry; thus applying emollients after using this ingredient may be helpful. Many of the newer benzoyl peroxide products have moisturizing agents added to

prevent excessive drying. My favorite benzoyl peroxide product to use in seborrheic conditions is SulfOxyDex (DVM Pharmaceuticals) because of the additive or possibly synergistic effects that the sulfur adds to the benzoyl peroxide. The most common products used are listed in the antibacterial shampoo section.

Zinc Gluconate and Pyridoxine Shampoos

Zinc gluconate has antiseborrheic properties. Zinc is a type 1 5 α -reductase inhibitor, down-regulates sebum production, and is used in human dermatology to treat acne vulgaris, both topically and orally. Vitamin B₆ (pyridoxine) also plays a role in sebum secretion, and there is a synergistic effect of unknown mechanism with zinc. Zinc gluconate and vitamin B₆ are combined with essential fatty acids in a newer shampoo that has both antiseborrheic and antibacterial properties (Keratolux [Virbac]).

Phytosphingosine Shampoos

Products containing PS have just been released (Douxo, Sogeval) and, as mentioned previously, have been used for both seborrheic and allergic skin disease conditions. PS is available in shampoo—spray-on and residual spot-on formulations. My preliminary clinical evaluation has shown great promise with these products in all forms of seborrheic skin conditions. In addition PS-based products also have antimicrobial activity, which can help many seborrheic skin disease conditions (see below).

SHAMPOOS FOR INFECTIOUS DISEASES

Pyoderma

Topical therapy can be used in all types of pyoderma. It usually decreases bacterial counts and reduces surface colonization of bacteria, thus helping to prevent or reduce the incidence of recurrences. There are many different topical antimicrobial vehicles; however, shampoos are the most practical and effective (Table 91-3).

The frequency of shampooing for pyoderma depends on the severity of the case and the owner's willingness to do the work. Deep pyoderma cases benefit from frequent bathing (every 2 to 3 days) initially, followed by a weekly maintenance. Most cases respond best if the overlying hair is clipped before bathing. The most common antibacterial agents found in shampoos include benzoyl peroxide with or without sulfur, chlorhexidine, ethyl lactate, and triclosan.

Benzoyl Peroxide

Benzoyl peroxide is considered the most effective for *Staphylococcus intermedius*. In addition to its antibacterial effects, it is an excellent follicular flushing agent, which promotes removal of inspissated debris and is comedolytic. It also has excellent keratolytic and degreasing effects. It is available in several different products: OxyDex and Sulf/OxyDex (DVM Pharmaceuticals), Pyoben (Virbac), Benzoyl Plus (Vetoquinol), DermaBenSs (DermaPet). It can be drying and irritating in some cases, but this is rare with the products listed since most have additional moisturizing agents to counteract this.

Table 91-3

Antimicrobial Shampoos

Product	Ingredients/Uses (Active Ingredients)	Formulation	Manufacturer
Sulfoxydex, Oxydex	Benzoyl peroxide 2.5%/5%	Shampoo/gel	DVM Pharmaceuticals
Pyoben	Benzoyl peroxide 3%/5%	Shampoo/gel	Virbac
Benzoyl Plus	Benzoyl peroxide 2.5%	Shampoo	Vétoquinol
DermaBenSs	Benzoyl peroxide 2.5%, sulfur/salicylic acid 1%	Shampoo	DermaPet
ChlorhexiDerm	Chlorhexidine 2%/4%	Shampoo/rinse	DVM Pharmaceuticals
Hexadine	Chlorhexidine 3%	Shampoo	Virbac
SebaLyt and SeboRx	Triclosan 2%/3%	Shampoo	DVM Pharmaceuticals
Etiderm	Ethyl lactate 10%	Shampoo	Virbac
Keratolux	Salicylic acid and zinc gluconate	Shampoo	Virbac
Malaseb	Chlorhexidine and miconazole	Shampoo/rinse/towelettes/ pledgets	DVM Pharmaceuticals
Ketochlor	Chlorhexidine 2%, ketoconazole 1%	Shampoo	Virbac
Nizoral/Generics	Ketoconazole 1% and 2%	Shampoo	Janssen/Generics
Miconazole	Miconazole	Shampoo/lotion	Vétoquinol
Resichlor	Chlorhexidine 2%	Lotion	Virbac
Resizole	Miconazole 2%	Lotion	Virbac
Seba-hex	Chlorhexidine 2%, sulfur/salicylic acid	Shampoo	Vetoquinol
Malacetic	Boric acid 2%, acetic acid 2%	Shampoo/rinse/wipes	Dermapet
Douxo	Phytosphingosine/chlorhexidine 3%	Shampoo	Sogeval
Selsun Blue	Selenium sulfide 1%	Shampoo	Ross

Chlorhexidine

Another favorite antibacterial agent is chlorhexidine. It is less drying and irritating than benzoyl peroxide, but at the 2% concentration it is not as effective (Chlorhexiderm [DVM IVX Pharmaceuticals] and Hexadine [Virbac]). However, a 4% formulation has been quite impressive in clinical cases (4% ChlorhexiDerm, DVM Pharmaceuticals). Some formulations combine chlorhexidine with other products to give combined benefits. Sulfur and chlorhexidine (SebaHex, Vetoquinol), chlorhexidine and ketoconazole (Ketochlor, Virbac) and phytosphingosine and 3% chlorhexidine (Douxo, Sogeval).

Triclosan and Ethyl Lactate

Two other antimicrobial agents that have antibacterial effects are triclosan and ethyl lactate. Triclosan has less activity against *Staphylococcus* than the agents listed previously, and it is not effective against *Pseudomonas* spp. Ethyl lactate is liposoluble and penetrates hair follicles and sebaceous glands. It is hydrolyzed by bacterial lipases into lactic acid and ethanol. This lowers the skin pH, thereby inhibiting bacterial lipases, making it bactericidal and bacteriostatic. These products are considered nonirritating. However, they are not routinely selected for most *S. intermedius* pyoderma cases because of the superior effectiveness of the previously mentioned products. There are a few products that contain triclosan (SebaLyt and SeboRx, DVM Pharmaceuticals) and ethyl lactate (Etiderm, Virbac).

Salicylic Acid and Zinc Gluconate

A shampoo that has both antimicrobial and antiseborrheic effects is Keratolux (Virbac). Keratolux is a salicylic acid, zinc gluconate, and B₆ vitamin- and fatty acid-based shampoo. In a study comparing it to a salicylic tar-based shampoo, it had similar antimicrobial and antiseborrheic effects (Reme, 2005).

Phytosphingosine

The PS-containing products (Douxo, Sogeval) mentioned previously also have good antimicrobial properties in helping to control surface *S. intermedius*, *Escherichia coli*, and *Pseudomonas aeruginosa*. When combined with 3% chlorhexidine, there is an additive effect.

Malassezia Dermatitis

Malassezia dermatitis is frequently a recurrent skin infection associated with an underlying disease process. Topical therapy is useful in eliminating infection, but it may also be beneficial when used routinely to help prevent recurrence of infection. For generalized infections shampoo therapy is most useful, whereas localized infections may benefit from use of other vehicles such as creams, lotions, pledgets, towelettes, and sprays. Dogs with generalized infections show the most rapid response when topical therapy is used in conjunction with systemic therapy.

Chlorhexidine, Miconazole, Ketoconazole, Acetic Acid, and Selenium Sulfide

When chlorhexidine is being used to treat *Malassezia* dermatitis, a 2% to 4% formulation is required. Some of the more effective products combine chlorhexidine with other antiyeast or antimicrobial agents: chlorhexidine and miconazole (Malaseb [DVM Pharmaceuticals]), chlorhexidine and ketoconazole (Ketochlor, Virbac), and chlorhexidine and phytosphingosine (Douxo/chlorhexidine PS, Sogeval). Miconazole and ketoconazole are both available in shampoo formulations as only the active ingredient (miconazole shampoo [Vetoquinol] and ketoconazole [Janssen]). An alternative to these products for control of *Malassezia* dermatitis includes acetic acid-based products (Malacetic, DermaPet) and selenium sulfide shampoo (Selsun Blue, Ross).

Dermatophytosis

For generalized infections, topical shampoo therapy can be used as an adjunct to systemic therapy in the management of dermatophyte infections. The main goal of topical therapy is to decrease spread of infection and environmental contamination. Clipping the hair coat is recommended in generalized infections to decrease shedding of contaminated hairs into the environment; however, some studies have demonstrated that shaving infected cats with localized lesions can actually cause the lesions to spread. Although many specialists use shampoo therapy for dermatophytosis, others consider it controversial since there are anecdotal reports that it can cause lesions to spread because of vigorous rubbing. Most also advocate leave-on sprays or dips following shampooing for additional residual activity. All of the same products listed under the *Malassezia* section can be used for dermatophytosis. Most of these are shampoos or leave-on rinses or sprays that contain single active ingredients or combinations containing miconazole 1% to 2%, ketoconazole

1% to 2%, chlorhexidine 2% to 4%, clotrimazole 1% to 2%, enilconazole 0.2%, or lime sulfur 4%.

CHAPTER 92

Allergen-Specific Immunotherapy

CRAIG E. GRIFFIN, *San Diego, California*
JOHN M. MACDONALD, *Auburn, Alabama*

Allergen-specific immunotherapy (ASIT) is often used in the management of canine and feline atopic dermatitis. ASIT can be defined as the practice of administering gradually increasing quantities of an allergen extract to an allergic subject. The goal of ASIT therapy is to reduce or eliminate the clinical signs associated with subsequent exposures to the causative allergen. This mode of therapy carries potential advantages and some disadvantages compared to other forms of therapy for atopic skin disease. However, it is generally considered the treatment of choice before instituting lifelong continuous glucocorticoid or cyclosporine therapy since ASIT creates less adverse effects than systemic treatments.

The application of ASIT is predicated on the controlled delivery of clinically relevant allergens. These allergens are constituted within a sterile protein-containing liquid that is an extract of the allergenic material, referred to as the allergen solution. Since the actual allergen is part of this protein complex, the volume of allergen in solution is related to the amount of protein in the liquid

extract. The protein content is commonly expressed (in the United States) as protein nitrogen units (PNU), with higher numbers ostensibly equated to a higher allergen protein concentration within the solution. Weight relative to volume is another method for reporting the level of protein. The majority of dermatologists and allergen supply companies in the United States treat with aqueous allergens, which is the basis of this discussion.

ASIT therapy is initiated by injecting the most dilute or lowest protein concentration allergens first and then gradually increasing the volume of injections through the relative concentrations of the protein within each solution until a maintenance dosage is reached. A treatment protocol detailing the amount and interval of injections to be administered from the respective concentration is followed until the maintenance dosage is reached. Many protocols call for initial injections given as frequently as every other day to weekly. Once a maintenance dosage is reached, the time between injections increases, with intervals of 7 to 21 days commonly used. Less allergen is generally administered when the interval between injections

is shortened. Allergen supply and serum allergy testing laboratories usually provide an ASIT treatment protocol.

ALLERGEN-SPECIFIC IMMUNOTHERAPY PROTOCOLS

Currently a large number of protocols for aqueous ASIT are available. The schedules should emphasize what clients should watch for and report (Box 92-1), including scoring the degree of pruritus as an "Itch Score." Clients also need to be reminded of reevaluation schedules. I (CG) use one protocol for large dogs, a different one for small dogs (under 20 pounds of body weight), and a third protocol for cats (Boxes 92-2 to 92-4). Author JM uses a three-vial protocol for dogs over 20 pounds and a second protocol for dogs under 20 pounds and cats (Boxes 92-5 and 92-6). Whichever protocol is followed, the clinician must recognize that any protocol is simply a starting point and adjustments may and often should be made based on the patient's response to ASIT. The following guidelines apply to aqueous ASIT; the doses and injection intervals of non-aqueous ASIT differ, but the principles of when and how to adjust are similar.

ADJUSTING THE ALLERGEN-SPECIFIC IMMUNOTHERAPY SCHEDULE

ASIT can be adjusted in a number of ways. The volume of solution and therefore the total amount of protein injected can be changed. The interval between injections can be altered so that injections are given more or less frequently. A second individual set of allergens may be started along with (or combined with) with the original set of allergens. Finally, allergens can be remixed or reformulated, with the concentration of antigen (protein level/volume) increased or decreased or the allergen mixture modified. Modifying

Box 92-1

Allergen-Specific Immunotherapy Home Therapy: Information for Clients

- Grade itching on an "itch scale" of 0 (none) to 10 (severe scratching).*
- Call in 4 weeks and report the grade of itching.
- Call if itch score increases by more than two levels
- Call before giving any more shots if there are adverse reactions.
 - Vomiting, diarrhea, anxiousness, weakness are possible reactions.
 - NOTE: Reactions will usually occur within 1 to 2 hours after shot is given.
- Recheck appointments should be scheduled around day 60 and day 120 of therapy.
- Watch for the pattern of itching in relation to when shots are given.
 - Itch score increases before the next shot is due or after a shot is given.
 - Itch decreases after a shot is given.

*Baseline should be determined after control of any skin infection or control of any fleas

the volume or the interval is the simplest approach and does not require reformulation.

Clinical responses to ASIT therapy often dictate protocol adjustments. Reasons to adjust ASIT vary but mainly relate to improving efficacy or decreasing adverse reactions. In some instances the interval of therapy is modified because of convenience. A common reason to adjust ASIT is some clinical improvement after an injection followed by an exacerbation in symptoms "X" days later. In this situation we alter the injection schedule to the interval of "X" or "X" plus 1 or 2 days when "X" is less than 5 days. Alternatively, if the problem persists, the interval may be changed to exactly "X" days. The volume given is determined by the basic rules described in the following paragraphs; but in general, when the interval is shortened, the amount given is also decreased. It may be more convenient to choose a schedule of twice weekly such as every Wednesday and Saturday when the interval is less than 5 days. The animal may stay at this shortened interval long term; or, if preferred by the owner, once the animal has done well for 3 months, the interval between injections may again be lengthened since the response of some animals to ASIT continues to improve for a couple of years. Some animals also have seasonal exacerbations of their atopic disease that may result in a shorter interval during the bad season and longer intervals in the "good" season, with the maximum interval being 30 days.

Often adjustments are made based on adverse reactions; therefore it is essential that the owner be aware of potential adverse reactions.

Adverse Reactions

Adverse reactions in humans are observed and categorized as either local or systemic. Local reactions characterized by erythema and swelling at the injection site are reported as fairly common. Systemic reactions are much less common and are usually mild, with rapid response to medications. Symptoms may include increased allergy symptoms such as sneezing, nasal congestion, or urticaria. Anaphylaxis is referred to as rare. Most systemic reactions develop within 30 minutes of allergen administration. Fatal reactions are reported in humans but are considered even rarer. A report of one fatality per 63 million injections supports the infrequent occurrence (American College of Allergy, Asthma and Immunology, 1997). Risk factors associated with the fatalities include dose errors; seasonal exacerbation of allergic disease, especially symptomatic asthma; high degree of allergen sensitivity; injections from a new vial of allergen; and β -blocker use. Nonfatal systemic reactions are more common and have been reported at a rate

of 0.05 to 3.2 per 100 injections (mean of 0.5%) (Stewart and Lockey, 1992).

Adverse Reactions to Allergen-Specific Immunotherapy in Dogs and Cats

Unfortunately there are limited records of adverse reactions to ASIT, and much of the consensus is based on clinical observation and anecdotal reports. The most common reaction noted, particularly in the dog, is pruritus. The pattern of itching may be typical of the atopic distribution (face, ears, axillary, inguinal, feet, and extremities) or generalized. The pruritic event may be spontaneous and related to the allergen injection or more persistent without any noticeable relation to the allergen injection. The most common association is toward the conclusion of the induction schedule as the maintenance regimen is reached. The intensity of the pruritus may be greater: (1) at the phase of induction with the introduction of the vial containing the next level of concentration; (2) during the continuation of therapy with a new replacement vial of allergen solution; (3) during the time when a higher intensity of natural allergen load occurs; or (4) when

concurrent annual infectious disease immunizations have been administered. Smaller dogs (less than 10kg) may be at greater risk. It may be difficult to determine the contribution of the allergen therapy to the increasingly pruritic animal during its normal allergic season. In these cases temporary discontinuation of allergen injections usually results in improvement because the animal goes back to its baseline level of disease within several days. Routine annual immunization coincidental to the allergen therapy, particularly toward the end of the induction phase, may contribute to the elicitation of pruritus or other adversities. Exposure to other offensive allergens such as fleas or food may further confuse the association of allergen therapy with the clinical features. The incidence of pruritus as an adversity of allergen immunotherapy is not completely known but appears to be common. In Rosser's study (1998) of 52 dogs that were maintained on immunotherapy greater than 6 months, 26 (50%) had adverse reactions, 11 (21%) and 15 (29%) a persistent worsening of pruritus. Eight dogs (15%) definitely had pruritus as part of the adverse reaction. The number of dogs with persistent increasing pruritus was not determined. Well-designed prospective studies evaluating adverse reactions in dogs and cats have not been reported.

The therapeutic intervention in the event of speculated or substantiated adverse reaction is dictated by the extent of the clinical features observed. Conservative therapy in events of mild pruritus with relevant association to the injections may require only decreasing the volume of allergen injected. Reduction should be at least to the previous level at which no adversity was observed, or it may require an empiric reduction by 50% or more. Some

specialists recommend treatment with no dose change, dose changes in addition to the integration of antihistamine therapy, and/or low-dose alternate-day oral glucocorticoid therapy and topical antipruritic treatment. We prefer lowering the volume given to levels that do not stimulate an adverse reaction. In the event of reaction that occurs during the induction phase, it may be necessary to prepare a lower concentration or resort to the previous dilution for continued therapy, with the intent to continue a slow incremental increase to reach at least a low volume (0.1 ml) of the typical maintenance dosage of 10,000 to 20,000 PNU/ml. In rare cases this cannot be achieved because of persistent reactions; some animals remain on more dilute allergen doses and generally require injections more frequently, sometimes as often as every 2 to 4 days.

More substantial adverse reactions (i.e., urticaria, angioedema, vomiting, or diarrhea) may be observed. Some breeds seem to be more predisposed for these reactions. Our experience includes dachshunds, boxers, Boston terriers, schnauzers, and English Bulldogs in this higher-risk category. These reactions are cause for greater concern and should be taken seriously because they border on a systemic reaction. Allergen therapy should be discontinued temporarily, and systemic antihistamine and glucocorticoid therapy should be integrated in the treatment plan. Parenteral administration of drugs may be indicated for more urgent care or emergency therapy. Reinitiation of allergen therapy should be considered when the adversity has been resolved. Recurrence can be minimized by adjusting the allergen dosage to 50% of the volume causing the reaction; this injection should be given in the clinic or hospital with monitoring. Some specialists also pretreat

½ hour before future injections with an antihistamine with or without concurrent glucocorticoid therapy.

The most severe reaction is anaphylactic shock, which manifests as hyperventilation, collapse, or pale mucous membranes with weakness. The following protocols should be considered in the event of severe systemic or an anaphylactic reaction. For a peracute reaction epinephrine should be administered. The dose is 0.01 mg/kg or 0.1 ml/kg of a 1:10,000 concentration intravenously. The solution is made by diluting a 1:1000 concentration using 1 ml of epinephrine in 9 ml of saline. The volume of milliliters to be administered equals the body weight in kilograms divided by 10. A tongue vein may serve as a route if unable to obtain intravenous access, or injection directly in the tongue parenchyma may also be considered. Alternatively the epinephrine is administered via an endotracheal tube to the level of the carina, using a male urinary catheter. Transcutaneous injection into the trachea is another route but may require an increased dose (doubling). Fluid therapy should be initiated at 1.5 to 5 ml/kg/minute or 90 ml/kg/hour for a dog or 50 ml/kg/hour for a cat. If hypotension is unresponsive to this volume of fluids, a colloid may be added (either pentastarch or hetastarch, 5 ml/kg for dogs or 2.5 ml/kg for cats, in a bolus with as much as 20 ml/kg for dogs or 10 ml/kg for cats over 15 minutes). Blood pressure and physical response should be monitored. Antihistamine therapy may be integrated with parenteral administration in an anaphylactic patient. Diphenhydramine is suggested at 1 to 2 mg/kg with a maximal dose of 50 mg intramuscularly every 8 hours. Caution is expressed for intravenous administration because of hypotensive effect and vomiting. Tripelennamine HCl may be administered intravenously or intramuscularly at 1 mg/kg every 12 hours. Glucocorticoid therapy is routinely included in the treatment regimen for an allergic reaction. Prednisolone sodium succinate or methylprednisolone succinate at 2 mg/kg intravenously should be administered over 15 to 20 minutes. An intramuscular injection may be the alternate route in the event of inaccessible intravenous administration. Dexamethasone sodium phosphate may be administered slowly intravenously at 0.25 to 0.5 mg/kg. Alternatively intramuscular or subcutaneous administration may be necessary. Corticosteroid therapy may be useful in controlling ongoing anaphylaxis, but its benefit in reversing the life-threatening situations is questionable. Withholding glucocorticoid therapy until the intravenous volume has been reestablished is recommended since corticosteroids may cause hypotension. Dopamine is suggested for protracted hypotension by some emergency manuals, using an initial dose of 2-10 mcg/kg/minute. Referral to an emergency manual is recommended to obtain further information on infusion procedures with dopamine. Repeat therapy with epinephrine at 1 ml/kg/hour continuous-rate infusion is preferred by some emergency clinicians over dopamine, with the addition of 4 mg of epinephrine to 1 L of saline. Emergency situations should always include critical monitoring of hematocrit, total solids, and urinary output. Other emergency therapy may be indicated in the event of protracted respiratory distress (refer to appropriate emergency manual). Famotidine may be integrated at 0.5 mg/kg every 12 hours if gastric ulceration is suspected.

Strong consideration should be given to alternative therapy for the atopic problem in lieu of continuing with allergen immunotherapy.

Extreme caution should be exercised if allergen therapy is to be continued in cases with severe systemic reactions. It is advisable to conduct the treatment under the direct supervision of a veterinarian in a hospital environment equipped for handling allergic emergencies. Significant reduction of allergen must be considered to avoid recurrence of the anaphylaxis. Pretreatment with antihistamine and glucocorticoid is advisable. A well-established protocol should be determined if therapy is to be continued by the pet owner. Pretreatment with antihistamine and glucocorticoid is necessary until such time as it seems tolerance has been reached.

Determining the Maintenance Frequency

For many dogs and cats the maintenance dosage (volume of 10,000 to 20,000 PNU/ml) is reached by following the protocol; if no adverse reactions are seen, a final volume of 1 ml in large dogs, 0.7 ml in small dogs, and 0.5 ml in cats is attained. In others the maintenance dosage is determined based on adverse reactions as previously described. Further adjustments are then made to the intervals between injections. If the animal is doing well for the complete duration between shots, the time between injections is gradually lengthened, generally by 2 to 3 days. The new interval is used for three consecutive injections; if the animal is still doing well, more days are added to the interval between injections. The maximum interval is 30 days since longer intervals may allow the allergen solution to become outdated and adverse reactions become more of a concern if errors are made in doses given and intervals not accurately followed.

Determining the Maintenance Dosage

In general, the goal is to reach 1 ml of a 10,000 to 20,000 PNU/ml allergen solution or to find the highest injectate volume that will not aggravate clinical signs. The aim is for a maintenance volume to average about 0.05 ml/day; most dogs receive an average of 0.05 to 0.1 ml/day, with occasional cases going as low as 0.03 ml/day. Once the maintenance dose is identified, the frequency is then adjusted so that the improvement is maintained over the time between injections. If the patient is not responding, the maintenance dosage is given at shorter intervals; if the maintenance dosage is 1 ml, this is 10 days and if the maintenance dose is less than 1 ml, the interval is by the formula of 1 day for every 0.1 ml in the maintenance dose. In dogs that still show no response, 0.5 ml is given every 5 days for 1 month; if there is still no response, 0.7 ml is given every 5 days. If the above is unsuccessful the therapy will likely be ineffective.

Predicting Long-Term Maintenance Cost of Allergen-Specific Immunotherapy

Understanding this general dosage range makes it easy to predict the long-term cost of ASIT therapy because in most cases the volume will be 1 to 3 ml per month. The ASIT cost then includes the cost of the liquid, the cost for syringes based on ASIT frequency of injections per month,

and the cost of reevaluations. There is no need to monitor any blood work or urinalysis in dogs on long-term ASIT since no known adverse reactions are detectable by these tests. When the pet has an excellent response to ASIT with total control (15% to 20% of cases), only the cost of 12 to 36 ml of allergen, the syringes, and one annual recheck is involved in controlling the pet's atopic disease. In many other cases (40%) the animals are much improved but still have an occasional exacerbation of their allergic signs, possibly inducing secondary infections that may require 2 to 4 weeks of therapy. In these cases the cost of this short-term therapy once or twice a year must also be considered in determining long-term management costs.

Concurrent Therapies

Generally if the pet's allergy symptoms are not severe, systemic antipruritic therapies are avoided in the initial induction until it is determined that the maximum volume and concentration of allergen solution that does not stimulate an adverse reaction has been reached. In cases with moderate-to-severe pruritus, compassionate use of concurrent medications is indicated. These are avoided in other cases so that mild adverse reactions and patterns of pruritus associated with injections may be observed. Although concurrent administration of systemic antihistamine is preferred during the period of dosage adjustment, systemic oral glucocorticoid therapy may also be used. Prednisone or prednisolone at 0.5 to 1 mg/kg (1 to 2 mg/kg in cats) every other day is a conventional regimen that in our experience does not pose a detrimental effect on the overall response to allergen treatment. Many times the use of glucocorticoid therapy is for a short term. The integration of oral methylprednisolone may be beneficial at a low dosage of 0.1 to 0.2 mg/kg

every other day in combination with daily oral antihistamine therapy. Cyclosporine (5 mg/kg daily for 6 to 8 weeks and then every other day for maintenance) may also be used; although, if not previously used, there may be a 7- to 14-day period before it shows efficacy at controlling pruritus. There is no evidence that these therapies interfere with successful response to ASIT, and at least in humans bee venom immunotherapy with concurrent antihistamine therapy appears to improve the response.

The integration of therapeutic modalities is often a necessity for optimal control of atopic dermatitis in the dog or cat. ASIT continues to remain a mainstay in the choices of specific treatment, with the appeal of positive response rate and low observation of adversity. Providing injection therapy at a convenient interval is often an appealing alternative to more aggressive oral therapy for the treatment of a disease with a protracted course. The repetitive and intermittent evaluations of the animal are a prerequisite to maximal control. Responsiveness to treatment modification and observation for complicating problems (bacterial pyoderma, cutaneous *malassezia*, dermatophytosis, or demodicosis) with proper response accounts for an increase in the control of atopic animals.

CHAPTER 93

Topical Immunomodulators

JOEL D. GRIFFIES, *Tustin, California*

TOPICAL IMMUNOMODULATORS

Immunomodulators have been defined as drugs used for their effect on the immune system. This effect may be immunosuppressant as in the case of corticosteroids and calcineurin inhibitors or immunostimulatory as occurs with the use of vaccines or drugs such as imiquimod. With topical application these drugs are allowed to have a focused effect at the site of disease with, in many cases, significantly

decreased or no systemic effects. Although a large body of research has developed on the use of these compounds in humans, the indications for topical immunomodulators in animals is just emerging. However, the mechanism of activity, minimal absorption, and increased potency of these drugs, as well as early clinical and anecdotal evidence makes these drugs attractive, and suggest that a number of applications will likely be adapted to veterinary medicine and become useful tools for the practitioner.

Calcineurin Inhibitors

Calcineurin inhibitors, including drugs such as cyclosporine, tacrolimus, and pimecrolimus, are an important class of immunomodulators that have been at the forefront of this genre in the last few years (also see Chapter 55). Calcineurin is a key enzyme in the activation of T lymphocytes. It functions in the induction of gene transcription of a number of inflammatory mediators, including many interleukins (ILs) (e.g., IL-2, IL-3, IL-4), granulocyte-macrophage colony-stimulating factor (GM-CSF), tumor necrosis factor- α (TNF- α), and interferon- γ (IFN- γ). Calcineurin inhibitors function by binding to a carrier protein with a high affinity for calcineurin, preventing its activity (Fig. 93-1). They have also been shown to inhibit the activation of mast cells, basophils, eosinophils, keratinocytes, and Langerhans cells. Both cyclosporine and tacrolimus decrease the number and activity of epidermal dendritic cells and down-regulate the expression of the high-affinity immunoglobulin E receptor (F_c ϵ RI) on Langerhans cells. Calcineurin inhibitors have been used in both humans and animals for many years. Specifically the use of oral cyclosporine for atopic dermatitis (AD) has received much interest recently in veterinary medicine, whereas topical calcineurin inhibitors have been a hot topic in human dermatology literature.

Cyclosporine

Oral cyclosporine has been well studied for its role in managing AD and a number of other dermatologic diseases (see Chapter 84). It is a highly lipophilic cyclic polypeptide

with a molecular weight of 1202kd. Because of molecular size and structural and biologic differences from the other calcineurin inhibitors, its use as a topical treatment modality for inflammatory skin disease has been unrewarding and limited to only anecdotal reports of success.

Tacrolimus

Since its discovery in 1984, intravenous and oral formulations of tacrolimus have been used worldwide in the prevention of organ rejection following allogeneic transplants in humans. Although similar to cyclosporine in its mechanism of activity, it is structurally different. Tacrolimus is a hydrophobic macrolide lactone with an atomic weight of 822kd (smaller than cyclosporine) and is well absorbed into the epidermis via topical administration. The potency of tacrolimus has been estimated at 10 to 100 times greater than cyclosporine. It is currently approved in the United States for use in humans with moderate-to-severe AD. In numerous large multicenter studies it has been found to have significant benefit in the treatment of both pediatric and adult atopic patients. More recently additional applications, including treatment of actinic (solar) dermatosis, psoriasis, and early stages of cutaneous T cell lymphoma have been reported. In veterinary medicine data regarding the use of topical tacrolimus is much more limited but shows promising findings in a number of applications.

CANINE ATOPIC DERMATITIS

Marsella and colleagues performed early studies with topical tacrolimus for treatment of AD in dogs. In the initial

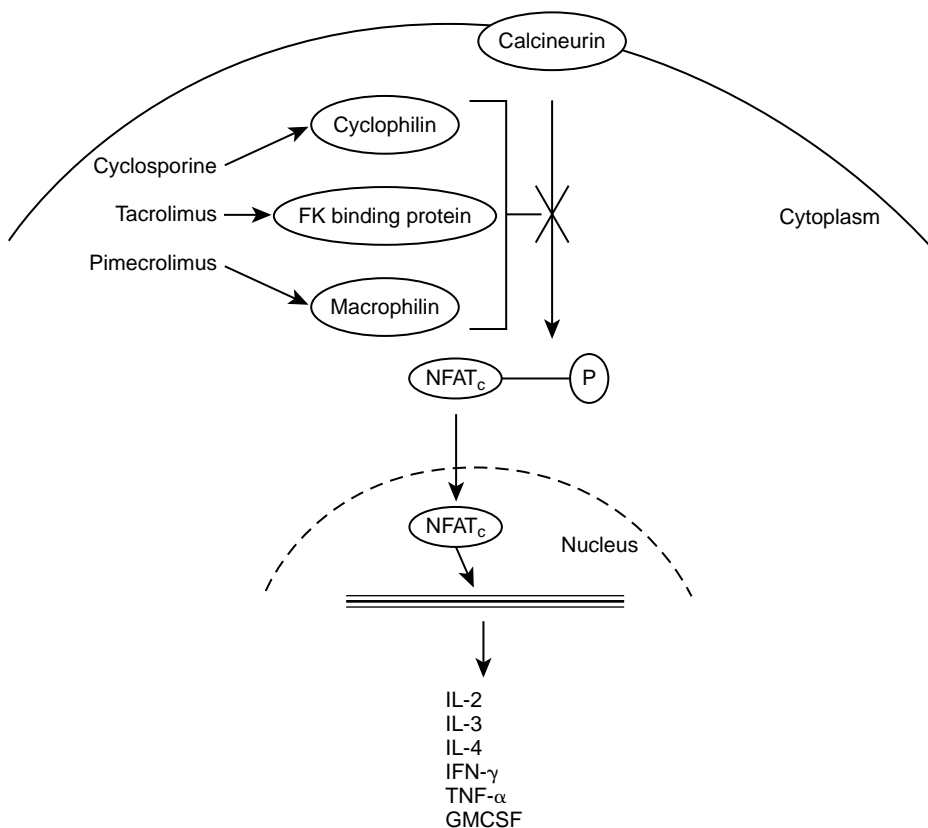

Fig 93-1 Mechanism of action of calcineurin inhibitors. GM-CSF, granulocyte-macrophage colony-stimulating factor; IL, interleukin; IFN, interferon; NFAT, nuclear factor of activated T cells; P, phosphorylation; TNF, tumor necrosis factor.

pilot study, using a 0.3% lotion formulated from the oral product, investigator scores for erythema decreased over placebo, but owner scores for pruritus were not significantly different (Marsella and Nicklin, 2002). However, a later randomized, double-blinded placebo-controlled crossover study using commercially available 0.1% tacrolimus ointment (Protopic, Astellas Pharma Manufacturing) found more encouraging results (Marsella et al., 2004). In this study treatment with topical tacrolimus was evaluated in 12 dogs that were diagnosed with AD. After 4 weeks of once-daily application, investigator scores for the tacrolimus-treated group decreased (improved) significantly, whereas no significant differences were detected within the placebo group. When dogs were divided based on severity of disease, those with generalized disease had significantly greater improvement than those with localized disease in both owner and investigator assessments. In conclusion, this study found that tacrolimus ointment decreased clinical signs of AD over a 4-week period with minimal adverse effects or safety concerns. A third study investigated efficacy of 0.1% tacrolimus ointment in treatment of localized lesions of AD on the front paws (Bensignor and Olivry, 2005). All subjects had lesions at other sites, but these were not included in either treatment or evaluation. At the end of the 6-week study the primary investigator found that all dogs who completed the study had a greater than 50% decrease in lesions evaluated (erythema, lichenification, oozing, and excoriations). This study did not evaluate pruritus. Although the results of these studies show benefit from topical tacrolimus, especially in localized AD, I have noted only limited benefit in the treatment of this disease. My experience corresponds with the observation that localized lesions may improve but progress is generally limited to decreases in erythema with less effect on pruritus. As a result, owners have not perceived a benefit substantial enough to warrant continued administration in most cases. Tacrolimus remains a potential option for treatment of localized AD, especially when trying to minimize the use of other treatment modalities with greater concerns for adverse effects (i.e., topical or systemic glucocorticoids), but at least in my practice it is not used as a sole therapy.

IMMUNE-MEDIATED DISEASES

An open-label study was performed by my practice evaluating 0.1% topical tacrolimus in the management of immune-mediated diseases such as discoid lupus erythematosus (DLE) and pemphigus erythematosus (PE). In this study 10 dogs with DLE and two dogs with PE were treated with the commercially available 0.1% tacrolimus ointment (Griffies et al., 2004). All cases had lesions localized to the nasal planum and adjacent regions of the muzzle. Owners applied 0.1% tacrolimus ointment to the affected areas every 12 hours. Each dog's lesions were assessed for degree of erythema, crust, ulceration or erosion, depigmentation, and scarring and were evaluated 2, 4, and 8 weeks after starting therapy. Ten of 12 dogs exhibited improvement in clinical lesions associated with PE or DLE (five excellent response, five partial response) over the 8-week trial. Of the dogs that showed progress, eight of 10 were treated with tacrolimus

alone by the end of the study and remained in remission at 12 weeks. Two of these cases followed for an additional 2 years continued to do well with topical tacrolimus alone. In my practice 0.1% tacrolimus has become a first-line drug for mild-to-moderate DLE. In mild cases it is often used alone every 12 hours for the first 2 weeks and decreased to every 24 hours, depending on progress. Once clinical lesions are resolved, many cases allow tapering to every other day or twice weekly. In moderate-to-severe cases 0.1% tacrolimus ointment is often used as an adjunctive therapy combined with tetracycline and niacinamide, vitamin E, or oral corticosteroids. In these cases topical tacrolimus may allow reduction of systemic therapies and can become a part of the longer-term maintenance of this chronic disease. Similarly in my practice topical tacrolimus has become an adjunctive to managing localized lesions of pemphigus foliaceus, but it is not considered a successful primary or exclusive therapy for this disease. However, it may assist in managing localized lesions that remain on the nasal planum, for example, without necessitating an increase in or modification of systemic medications such as corticosteroids or azathioprine when the majority of other lesions have resolved.

CUTANEOUS VASCULITIS

Cutaneous vasculitis may be present in a variety of clinical manifestations, including purpura, wheals, edema, papules, plaques nodules alopecia scarring, necrosis, and ulceration, often involving the extremities. One of the most common presentations seen by general practitioners and veterinary dermatologists is an ischemic dermatopathy often linked to vaccine administration. Lesions observed are the results of loss of blood supply from vasculitis or a vasculopathy. The prototypical form is that seen following rabies vaccination, usually 1 to 5 months after administration. A classic postvaccinal lesion may occur characterized by an annular hypopigmented or hyperpigmented area of alopecia that may also be indurated, erythematous, or scaly. Multiple distal lesions may occur with or without the presence of an injection site reaction. These commonly include lesions at the apex and often concave aspect of the pinnae, especially at the margins; but other areas such as the paw pads, tip of the tail, periocular region, and junction of the nasal planum and haired skin may also be involved. Topical tacrolimus has been especially useful in managing the mild-to-moderate pinnal lesions associated with this disease. Twice-daily application of the 0.1% ointment to crusted, indurated, and erythematous lesions typically affects improvement in these lesions within 2 to 4 weeks. Because of the ischemic nature of the lesions seen, some scarring, alopecia, or hyperpigmentation may be expected to remain even after the lesions are no longer active. In more severe cases topical tacrolimus therapy is often combined with other systemic therapies. Similar benefit has been seen in decreasing edema and erythema associated with early lesions associated with rabies injection site reactions. Alopecia again is expected to persist. With the more aggressive proliferative thrombovascular necrosis of the

pinnae, topical tacrolimus has been less effective since these cases typically need a more aggressive systemic therapeutic approach.

PERIANAL FISTULAS

Perianal fistulas are chronic, painful, often progressive inflammatory lesions of the perianal, anal, and perirectal tissues (see also Chapter 122). This condition has been reported most commonly in the German shepherd dog but have also been observed in Irish setters, Labrador retrievers, Old English sheepdogs, Border collies, bulldogs, and others. Lesions may vary from superficial microscopic fistulas to large ulcerations and sinus tracts and often are complicated by secondary bacterial infection. Although a specific etiopathogenesis has not been recognized, most recent efforts suggest an immune-mediated component. Clinical signs may include tenesmus, dyschezia, constipation, excessive perianal licking, and increased frequency of defecation. Previous therapies have included a variety of surgical methods, including excision, cryotherapy, chemical cauterization, and laser surgery. Reported remission rates from surgical therapy vary greatly (48% to 97%) along with complication rates (13% to 100%) and recurrences (13% to 56%). More recently medical therapies for this disease have produced more encouraging results. Most notably the use of cyclosporine with or without ketoconazole has shown substantial success in improving and resolving the lesions and clinical signs associated with perianal fistulas.

As reviewed earlier, the similar mechanism of action of topical tacrolimus makes it a good choice for this disease. Misseghers, Binnington, and Mathews (2000) reported clinical observations of 10 dogs treated with a 0.1% topical tacrolimus ointment formulated from the oral product before the release of the commercial ointment. As a sole therapy in this case series, five of 10 dogs had a complete response, and four of 10 had a partial response. In our practice we have found the 0.1% commercially available tacrolimus ointment to be a useful tool for perianal fistulas. However, because of the discomfort often associated with these lesions, the use of any topical medication as an initial therapy is less successful. A more practical protocol is to use oral cyclosporine alone (5 to 7 mg/kg daily) or oral cyclosporine (1 to 3 mg/kg daily) in combination with ketoconazole (5 to 10 mg/kg daily, respectively) initially. Once lesions are seen to improve, tacrolimus may be added once or twice daily. This allows reduction of cyclosporine, an often cost-prohibitive drug, while continuing to show progress. In my experience long-term maintenance has been possible using tacrolimus alone daily to two or three times per week.

EMERGING THERAPIES

Metatarsal Fistulation of German Shepherd Dogs

Metatarsal fistulation is an uncommon condition reported in German shepherd dogs. It has been suggested as a familial disorder of collagen caused by similar ancestry and antibodies against types I and II collagen found in dogs studied. Affected dogs develop fistulous tracts proxi-

mal to the metatarsal pads that typically have a serous or serosanguinous discharge. Therapies described for the management of this condition include antibiotic therapy along with oral immunomodulators such as corticosteroids. Researchers reported in a workshop that 0.1% topical tacrolimus was useful in these cases in an open clinical trial. At the end of 6 weeks of therapy, treated lesions in four of seven cases were in complete remission, and three had palpable but not visible lesions (Kwochka and Rosenkrantz, 2005). After following these cases for an additional 2 years I have been able to maintain them with intermittent topical tacrolimus therapy. Our success with this disease has been similar with positive results and an ability to improve and maintain plantar fistulas with intermittent topical tacrolimus therapy along with oral antibiotics for secondary bacterial infections when present.

OTHER APPLICATIONS

As a new topical tool for veterinary dermatologic conditions, tacrolimus has been used in a number of different types of cases. Anecdotal reports of success with topical tacrolimus include its use as an adjunctive in the treatment of acral pruritic nodules, combined with systemic antibiotics. I have found it only mildly useful in this application. Other areas may include assistance in management of actinic dermatosis and feline eosinophilic granuloma/plaque lesions.

Pimecrolimus

Although pimecrolimus (Elidel, Novartis Pharmaceuticals) has a virtually identical mechanism of action to tacrolimus and cyclosporine, no reports of its success in veterinary medicine have been published. It is produced commercially as a topical hydrophilic cream. In human literature side-by-side comparisons of pimecrolimus and tacrolimus found tacrolimus to be superior for the treatment of AD, although both drugs showed benefit. In my limited experience pimecrolimus has been less successful for the management of the diseases mentioned previously. Anecdotal reports suggest that the pimecrolimus molecule is not well absorbed when applied topically, which may explain these observations. Until more positive experience is obtained with this calcineurin inhibitor, I cannot recommend it.

Safety Concerns

In 2002 the Food and Drug Administration required a black box label to be applied to the packaging of topical calcineurin inhibitors, including tacrolimus and pimecrolimus. Unfortunately, based on a number of independent reviews, these concerns are largely unfounded. The potential risk of malignancies, especially lymphoma, with the use of systemic immunosuppressive drugs has been well studied. It has been noted with *oral* administration of cyclosporine, tacrolimus, azathioprine, and others. Studies supporting these concerns with topical immunomodulators have included the use of quantities overwhelmingly higher than those typically used in human medicine and

than those suggested for animals in this and other papers. Although the future of this concern will be determined only by retrospective studies, the opinion of those at the forefront of research with these drugs is that their use stimulates only minor concern in this area.

In the handful of recent studies using topical tacrolimus for dermatoses, none have noted significant systemic or topical adverse effects. Absorption of tacrolimus has been confirmed in some studies by measurable blood levels in treated patients. However, these levels have remained far below previously established toxicity levels and have had no effect on routine complete blood count and biochemical parameters. This information suggests that use of topical calcineurin inhibitors is unlikely to predispose veterinary patients or their owners to lymphoma. However, I still recommend that they be applied with gloves and that owners wash their hands after handling them.

Imiquimod

In contrast to the calcineurin inhibitors, imiquimod is an immune response modifier that functions by *stimulating* or enhancing local innate immune response. An imidazoquinolineamine, imiquimod (Aldara, 3M Pharmaceuticals) has potent antiviral and antitumor activity in animal research models. It has been shown to be a ligand for toll-like receptor (TLR) 7. Activation of TLR 7 results in cell-mediated immunity facilitated by T helper lymphocytes and can result in tissue-specific apoptosis. It is approved for the topical treatment of external genital and perianal warts in humans (commonly caused by human papillomavirus), as well as superficial basal cell carcinoma and actinic keratosis. Topically applied imiquimod can induce cells, including keratinocytes, to synthesize and release cytokines, including IFN- α , IL-6, and TNF- α among others. Although not antiviral itself, the induction of these cytokines, specifically IFN- α , inhibits viral replication and promotes stronger cell-mediated immune responses. A component of the innate immune system, IFN- α helps infected cells and their neighbors eliminate virus without a specific cell-mediated immune response. The cells respond as though they have been infected and begin making IFN- γ and other cytokines, which help to clear viral pathogens and lesions caused by them. As a biologic response modifier and an agent fostering a cell-mediated immune response, imiquimod may also help treat other dermatologic disorders, infections, and neoplasms. To this end, imiquimod has been reported to aid in the treatment of a variety of human diseases, including squamous cell carcinoma in situ (Bowen's disease), basal cell carcinoma, molluscum contagiosum, actinic keratosis, and various forms of cutaneous lymphoma.

In animal models imiquimod also stimulates innate immune response by increasing natural killer cell activity, activating macrophages to secrete cytokines and nitric oxide, and inducing proliferation and differentiation of B lymphocytes (Sauder, 2000).

In veterinary patients reports of imiquimod are limited but again show promise. Similar to its use in humans, imiquimod has been a useful tool in managing localized disease associated with viral infection.

Squamous Cell Carcinoma In Situ (Bowen's Disease)

Squamous cell carcinoma in situ (Bowen's disease) is an uncommon disorder in cats linked to a papillomavirus. Lesions are often found on the head, neck, and forelimbs. Topical use of imiquimod has shown positive success in managing localized lesions. It has been my experience on occasion that sites distant to those treated may improve or resolve while other lesions are being treated. Because of concern for inflammation and irritation at the site of application, a protocol of intermittent application is typically used. This may include alternate-day or three times-a-week application or applications on 2 to 3 consecutive days followed by 2 to 4 days off. Limitations of this therapy include the high cost of imiquimod and small surface area that can be treated with the small volume of medication per packet. I commonly reseal an open packet and use it repetitively to treat smaller lesions. However, even with larger lesions, the cost of repeated topical application may be less than traditional or CO₂ laser surgery.

Feline Herpesvirus

Feline herpesvirus one (FHV-1) is a common cause of upper respiratory disease in domestic cats and an uncommon cause of cutaneous erosion and ulceration (see Chapter 99). The localized nature of cutaneous lesions when present makes this disease an excellent candidate for topical imiquimod. As seen with other conditions, application of imiquimod often incites an initial inflammatory response that appears to worsen clinical lesions. However, following the initial inflammation, lesions may heal and be replaced by localized scarring. In at least one case polymerase chain reaction for FHV-1 was positive from both the cutaneous lesion and the conjunctival sac (a known site of FHV-1 sequestration) before treatment and negative after treatment with imiquimod. This suggested that not only did lesions clear but that the immune response stimulated may have been able to clear the virus entirely. Whether this was a true finding or a temporary change is difficult to ascertain and warrants further investigation.

Canine Cutaneous Papillomatosis

Clinical syndromes associated with papillomavirus in the dog include oral papillomatosis, cutaneous papillomas, cutaneous inverted papillomas, and papillomavirus-associated canine pigmented plaques. Of these, cutaneous inverted papillomas and cutaneous papillomas have been managed successfully with imiquimod. In most cases seen, topical imiquimod has been used following recurrence after surgical excision of solitary lesions. Unlike the surgical procedures, when the recurrent lesions are cleared via topical imiquimod, further relapse has not been observed.

Other Potential Uses

Because of its innovative mechanism of action and the induction of an immune response by local cells, imiquimod is very likely to have a number of additional uses. Based on applications in human medicine, these may

include management of actinic keratosis lesions in dogs and cats. Recent reports of success with topical imiquimod in treatment of equine sarcoid have also been published (Nogueira et al., 2006).

CHAPTER 94

House Dust Mites and Their Control

WAYNE S. ROSENKRANTZ, *Tustin, California*

IMPORTANCE OF HOUSE DUST MITES IN ATOPIC DERMATITIS

House dust mite (HDM) hypersensitivities are extremely common throughout the world. In a review of 469 cases of atopic dermatitis (AD) at the Animal Dermatology Clinics of southern California, dust mites were the top reactors (*Dermatophagoides farinae* 55.2%, *Dermatophagoides pteronyssinus* 39.7%). In other reports positive skin tests or serum IgE specific for HDM allergens may be as high as 6% to 90% in canine AD cases. House dust allergy is common even in clean homes and is a major cause of year-round allergy symptoms for humans as well as pets. House dust is a mixture of many mites and their body part allergens. The most common HDMs belong to members of the family Pyroglyphidae and include *D. farinae*, *D. pteronyssinus*, and *Euroglyphus maynei*. Other mites of importance include some mites that have been classified as storage, mold, or grain mites belonging to the family Acaridae (*Acarus siro* and *Tryophagus putrescentia*) and mites belonging to the family Glycyphagidae (*Glycyphagus domesticus*, *Blomia tropicalis* and *Lepidoglyphus destructor*). Some of these can

be found in high levels outside food sources and are also considered environmental mites that could contribute to mite hypersensitivity reactions.

The concentration of dust mites in the home environment varies, depending on what part of the country or world in which one lives. Environmental factors such as moisture or humidity are very important. The most important antigen fractions come from *D. farinae* and *D. pteronyssinus* (Der f 1 and f 2, Der p 1 and p 2, and Der f 15, a high-molecular weight antigen). It is possible that some mites may be more resistant to dryer or less humid environments. *D. farinae* is considered more resistant to dryer climates and may still be found in desert climates such as Las Vegas, compared to its counterpart *D. pteronyssinus*. In more humid or subtropical environments *B. tropicalis* may be found and in some cases may be the most prevalent. The HDM content varies from home to home as well as within areas of the home, depending on the type of furniture, building materials, and presence of pets. The highest allergen concentrations are found in pillows, mattresses, carpeting, and upholstered furniture. Levels have also been detected in automobiles and on the hair coats and bedding of dogs (Randal et al., 2005).

There may be as many as 19,000 HDMs in 1 g of dust, but more typically 100 to 500 mites live in each gram of dust. Each mite produces about 10 to 20 waste fecal particles per day and lives for about 30 days. Egg-laying females can add 25 to 30 new mites to the population during their brief lifetime.

ISOLATED ALLERGENS AND METHODS OF DETECTION

Allergens are divided according to their chemical properties and allergen cross-reactivity; they have cross-reacting and species-specific epitopes. Antigens are named by mite species and group antigen designations (e.g., Der p 1, Der f). Group 1 antigens Der p 1 and Der f 1 are the most allergenic for humans; they are associated with or found in mite feces and probably represent intestinal enzymes cysteine protease. Group 2 Der p 2 and Der f 2 are more stable than group 1 in the environment; they contain molecules associated with male reproductive tracts and have more species cross-reactivity. The other classified allergens include group 3: fecal trypsin; group 4: amylase; group 6: chymotrypsin; group 8: glutathione-S-transferase; group 9: another serine protease (an important human allergen); group 10: tropomyosin; group 11: paramyosin; group 13: fatty acid-binding protein; group 15: chitinase; group 16: gelsolin; group 17: calcium-binding protein; and group 18: chitinase. There are other as yet unclassified or identified allergenic epitopes considered less important or minor allergens.

The current information about which antigens dogs react to would indicate little reactivity with groups 1 and 2 antigens. There are higher-molecular weight (HMW) allergens recognized by atopic dog sera (Nuttall et al., 2006). One of the HMW antigens has been characterized as Der f 15, a digestive chitinase (McCall et al., 2001). Other HMW antigens that may be important in the canine include another chitinase (Der f 18) and tropomyosin (Der f 10). These allergens may be very difficult to denature and destroy, creating more difficulty in elimination from the environment.

Currently identifying HDM allergens in the environment or on the pet is rarely performed, and the association between mite levels and clinical disease has not been studied in the dog as it has in humans. Therefore when HDM sensitivity is detected, HDM control is generally recommended when feasible and especially when it is the only or primary allergen to which the dog reacts. When the owner or clinician wants to identify mites in the environment, the following techniques are available: mite counts/gram of dust, specific antigen assay (enzyme-linked immunosorbent assay [ELISA] or amplified ELISA), and measurement of mite fecal matter, with measurement of fecal guanine levels. Dust and mites are usually collected with dust by vacuum techniques. Fecal material can be sampled with a semiquantitative measurement of guanine (fecal product) by a commercially available test kit (Acarex); less than 0.6 mg of guanine per gram of dust can be detected and provides an estimate of dust mite fecal antigens. Antigens by ELISA using monoclonal antibody reagents for groups 1 and 2 Der p and Der f antigens are available. Amplified ELISA detection threshold (300 pg/ml) using MITE-T-Fast (AVEHO

Biosciences) is a validated wipe test. This technique uses a porous sampling pin in association with an immunochromatographic test system that detects Der p 2/f 2 with sensitivity 62%—specificity 94% when compared with ELISA assay. It can be used to identify dust mite allergen levels on textiles such as carpets, furniture, or bedding or on a pet's hair coat. Although species specificity exists, some cross-reactivity may exist between HDM allergens or related allergens such as storage mites or even scabies or otodectes. These tests need to be reviewed carefully and always interpreted in conjunction with clinical history and physical findings.

CONTROL OF HOUSE DUST MITES IN THE HOME AND ON PET

Mite antigens are difficult to remove from the environment. Commonly recommended techniques such as vacuuming, steam cleaning, and dry cleaning are often ineffective. Even using acaricidal products and reducing home humidity do not always work. All methods have variable effectiveness, and their benefits in clinical control of related HDM hypersensitivities in humans are controversial. However, there is one study (Swinnen and Vroom, 2004) and some anecdotal reports that suggest that there is clinical value in HDM control for canine atopic dermatitis.

Basic strategies include reducing carpeting, textile furniture, regular washing of bedding, vacuuming, reducing humidity, and using mattress and pillow encasements. Elimination of carpeting and switching to hardwood or tile floors can be helpful. Elimination of upholstery furniture and switching to wood, vinyl, or leather are also recommended. Washing bedding weekly in hot water (130°F) kills mites and removes most allergens. Dry cleaning kills mites but does not remove all allergens. Vacuuming weekly removes only surface mites and allergens and may be more effective if used in conjunction with other acaricidal agents (see following paragraphs). Dehumidifiers and air conditioning can be helpful in trying to maintain the relative humidity below 50%. However, even when the home environment is controlled, it may not be possible to completely control the microenvironment on a mattress or mattress pad because of the humidity created by body temperature. Mattress and pillow encasements lower mite levels but are controversial on their effectiveness in clinical control of related HDM hypersensitivities in humans. Mattress and pillow encasements are occlusive, vapor-permeable, nonwoven synthetic or tight-weave fabrics with certified pore size (5 to 9 micron) and are available commercially.

More intensive methods of HDM control include the use of specific acaricidal and mite allergen denaturing agents. Their effectiveness has been more controversial. One of the more classic agents is benzyl benzoate. In one study (Swinnen and Vroom, 2004) HDM detection and control with benzyl benzoate (Acarosan spray, Allergopharma) and changing the pets' bedding showed that after treatment 29 out of 60 dogs sensitive to HDMs or storage mites, 48% showed no skin lesions or pruritus. Moderate results were achieved in 22 dogs (36%) (i.e., reduced pruritus and minimal skin lesions but still requiring

medication). This product has limited availability and is considered a potential carcinogen.

Borates have received a lot of attention for HDM control. In a noncontrolled pilot study I looked at sodium polyborates for HDM control in treated (six) and untreated (three) homes. HDMs and their antigens were assessed via direct counts and for guanine antigen levels via the (Acarex) test. Significant reduction in HDM levels occurred; however, allergen levels remained elevated but reduced. In another placebo-controlled study carpet pieces were inoculated with *D. farinae* and *D. pteronyssinus* and treated with disodium octaborate tetrahydrate (DOT). Pretreated and posttreated measurements at 2, 4, and 8 weeks showed marked reduction in total mite counts: 885 to 10, 17500 to 1100 mite/gram dust *D. farinae* and *D. pteronyssinus*, respectively (Arlian and Mills, 2001). A placebo-controlled 6-month study in 93 homes with active, placebo (water), and negative control groups showed promising results. Dust collected before and after every 2 months from carpets and sofas and live mites, total mites, and mite allergen levels were measured. DOT killed mites in carpets and sofas for up to 6 months; sofas were less affected. HDM allergen was significantly lower in the carpets and sofas at 6 months after treatment (Codina, et al., 2003).

Denaturing agents have also been evaluated to inactivate the protein moiety of the HDM allergen, and some have also been proposed to kill the live mites. Tannic acid is one such product that may perform both functions. However, it is very drying and has significant problems with staining of fabrics. Another denaturing agent (Allerase, Aveho Biosciences) contains a citric acid derivative with soybean-extracted fatty acids and fatty alcohol surfactants. The active ingredient in the Allerase product has been evaluated both clinically and in unpublished in vitro studies. One study evaluated the denaturing effects of this product on Der p 1 and p 2 and showed superior reduction of HDM allergens when compared to other denaturing agents, including tannic acid and benzyl benzoate (Williams, 2000). However, the same effectiveness on the more important canine allergens may not occur with this product because high-molecular weight allergens are more difficult to completely denature. This was supported by another canine in vitro study in which HDM allergen was exposed in a 1:2 and 1:4 dilution with Allerase overnight. Although there was a detectable reduction in immunoglobulin E reactivity, it was not considered significant (Esch, 2003). However, this study did not use full-strength concentration. Another study exposed HDM-allergic dogs to HDM extract applied to kennel floors and compared it to a placebo control. The results showed no statistical difference between the

groups. However, the concentration and volume of the product were used at lower than would approximate clinical applications (Marsella, Nicklin, and Lopez, 2005). I have been evaluating the effects of Allerase (spray and shampoo formulations) as a topical therapy directly on the hair coat and skin as a means of eliminating or reducing percutaneous absorption of allergen on the skin surface. This seemed appropriate based on the work showing the presence of HDM allergens on dogs' coats and bedding (Jackson et al., 2005; Randall et al., 2005). I and others have anecdotal experience of some dogs responding to these products and I currently recommend its use in all primarily HDM-positive dogs.

Although many insecticides and growth regulators are ineffective for the control of environmental mites, one insect growth hormone regulator, pyriproxifen (Virbac), has been advocated as an environmental method of HDM control. Although I have not used this product, it is a recommended treatment in Europe and the United Kingdom.

Topical Therapy of Otitis Externa

COLLEEN MENDELSON, *Tustin, California*

Canine ear disease is a prevalent and persistent problem and accounts for up to 15% of all canine veterinary case presentations. The large variety and quantity of veterinary topical otic preparations available demonstrate the demand for a wide range of therapeutics for this condition. Primary causes of otitis externa include hypersensitivity disorders (e.g., atopy, food allergy), parasitic diseases, and metabolic disorders (e.g., primary keratinization defects, hypothyroidism, hyperadrenocorticism). Perpetuating and predisposing factors such as proliferative changes, excessive cleaning, or the use of inappropriate cleaning products also contribute to the prevalence of ear problems. Otitis externa can also be secondary to an infection of the ear canal. *Malassezia pachydermatis* is the most common isolate from diseased ears.

Identifying and managing the primary disease(s) are the goals of treating most cases of canine otitis externa and are often sufficient to prevent recurrence if no perpetuating factors are present. However, even when the primary cause is identified and addressed, cases occasionally require continuous topical and/or systemic therapy. On the other hand, in some cases of allergic otitis, as well as other chronic primary conditions, controlling secondary infections is sufficient to alleviate clinical signs. Otic preparations are designed to either address an immediate infection/infestation or prevent recurrence in chronic disease. Otic preparations that address bacterial and/or yeast infections are usually combinations of corticosteroids and antimicrobials. Preparations designed for long-term control are combinations of mild cleansers, drying agents, or disinfectants and may contain antimicrobial agents.

Overall the therapeutic approach to chronic ear disease is truly an art, and there is no “blanket” approach for treating this condition. Each case represents varying levels of proliferation and exudate with a different degree of infection versus inflammation. Therapy needs to be targeted at each aspect of the condition. Becoming familiar with the products available and their effects is essential to formulating the best therapeutic plan for each patient. Since new products are introduced into the market each month, it is important to have a good relationship with the various industry representatives who can keep the practitioner updated on what is newly available and the advantages the products may provide.

GENERAL PROPERTIES OF TOPICAL FORMULATIONS

The Vehicle

As with all forms of topical therapy, multiple formulations and vehicles are used in otic products. Each has specific

properties that need to be considered when selecting an appropriate product. The various vehicles have different mechanisms for delivery of the active ingredients, as well as therapeutic, irritant, or cosmetic properties that determine their efficacy in practice. Various vehicles encountered in veterinary topical otic therapy include solutions/rinses, lotions, creams, emulsions, and ointments.

Rinses generally are formulated by diluting concentrated solutions or powders with water. These can be poured into the ear in large amounts and therefore are the most appropriate vehicle for cleansers. Lotions are liquids in which the active ingredient has been dissolved or suspended. Thus, when the liquid dries, a thin layer of powder is left in the ear. Lotions tend to be drying because of their alcohol or propylene glycol content. Generally a “cooling” lotion or solution tends to contain alcohol, whereas a “soothing” one does not. Creams, emulsions, and ointments are occlusive and prevent contact with the environment. Creams are least occlusive, and ointments are the most occlusive; emulsions have characteristics of both. In exudative cases, use of an ointment may be contraindicated since increased water loss and drying are desired.

Active Ingredients

Astringents, soothing agents, acidifiers, alkalizing agents, keratolytic agents, keratoplastic agents, antibiotics, antifungals, and antiinflammatory and antiparasiticide products all can be found in the enormous milieu of topical otic preparations. Often these products are combined. When a practitioner is choosing a topical otic product, the patient’s specific condition, as well as the practitioner’s familiarity with the product, must be taken into consideration. Practitioners and dermatologists occasionally prepare “in-house” otic remedies from injectable antibiotics or antifungal agents or mix a variety of available otic products to create a single mixture that targets their specific patient’s need. This practice is a controversial and extralabel use of these drugs and is a topic beyond the scope of this chapter. However, if this approach is taken, it is important to remember that the stability and efficacy of the active ingredients may be affected, and the client must be clearly informed of the off-label formulation.

TREATMENT OF INFECTIONS

Initial Approach

Cytology: Cytology is an inexpensive procedure that can be performed easily in house, allowing the practitioner to

make immediate decisions regarding treatments or further diagnostics; it should be performed with every reevaluation of the ear. Often the character of the infection or the degree of inflammation will change. Repeating cytology may reveal a change in the infectious organisms that indicates that a change in the topical antimicrobial is in order. In addition, the presence of various inflammatory cells could be a sign that an irritant or allergic/immune-mediated reaction might be present. If a practitioner is not comfortable making decisions based on his or her abilities, duplicate slides can be submitted to a commercial laboratory for corroboration.

Cleaning: Cleaning and removing purulent, ceruminous, or foreign debris from an ear canal before initiating therapy is imperative for effective management of otitis. In addition to being therapeutic, cleaning removes exudates that can not only prevent a thorough examination of the ear canal but also interfere (chemically and physically) with the therapeutic agents. Ceruminolytic agents used in the clinic can aid greatly in removing debris; however, use of the more potent ceruminolytic formulations is not generally recommended for home care by the client. Table 95-1 lists a variety of different cleansers that can be selected based on severity of debris in the ear canal and whether the product is to be used in the practice or at home by the owner. Numerous cleaning techniques are described in the literature (see Chapter 97).

Cleaning is imperative for successful therapy; however, excessive cleaning by clients is often a perpetuating factor in chronic recurrent otitis. It is generally found that the initial cleaning is best left to the clinician during the initial acute phase of therapy. Once the acute episode is resolved, clients can be given products and instructions to keep the ears from relapsing. Most cleansers should be used no more than two to three times weekly. In some cases of mild otitis secondary to mild seasonal allergies, regular cleaning should only be recommended during the offending season or not recommended at all. One of the exceptions to this rule is in cases of chronic ceruminous otitis (e.g., cocker seborrhea). In this case regular ear cleaning and maintenance by the client are extremely important if any kind of therapeutic success is to be achieved.

Antibacterial Therapy

Topical therapy of active infections is imperative to success. Systemic (oral or injectable) therapy is sometimes necessary but is unlikely to achieve therapeutic concentrations within the ear as a sole treatment modality (see Chapter 96). The antimicrobial agent best used is often chosen empirically based on cytologic examination of ear canal exudate and otoscopic evaluation of the ear canal. Bacterial culture and sensitivity results can be of value, especially when dealing with gram-negative organisms (e.g., *Pseudomonas* spp.) from the middle ear. However, sensitivity results of bacterial cultures may be misleading since topical antimicrobial concentrations are much higher than serum concentrations. Occasionally cultures need to be repeated because infected ear canals often contain numerous bacteria colonies with different resistant patterns that are not all represented with one single culture.

Several veterinary topical otic formulations contain antibacterial agents (Table 95-2). It is important to consider previous therapies the patient may have received for the infection, the type of bacteria encountered, and the degree of inflammation and amount of exudate in the ear canal. If the canals are severely inflamed, the patient will likely need to return on a weekly basis for cleaning and reevaluation until the bulk of the infection and inflammation is resolved. For more resistant bacterial infections, especially gram-negative infections such as *Pseudomonas aeruginosa*, pretreatment of the canal with a tromethamine ethylenediaminetetraacetic (Tris EDTA)-containing product before administration of a topical antibiotic is recommended. Tris EDTA has antibacterial properties but also acts synergistically with aminoglycosides and fluoroquinolones to increase their bactericidal activity. A product (T8 Keto) is available that contains both Tris EDTA and ketoconazole to help control mixed bacterial and yeast infections.

Antiyeast Therapy

Numerous products are available to address yeast otitis (Table 95-3). Many of these products contain potent, broad-spectrum antibiotics; however, the antifungal included is sometimes less potent against the commonly encountered yeast organism *M. pachydermatis*. On the other hand, in cases of mild allergic yeast otitis, decreasing the otic inflammation with a topical glucocorticoid alone can aid in the elimination of a yeast infection or overgrowth by controlling many of the inflammatory by-products on which yeast survive. In chronic recurrent yeast otitis the use of boric acid or acetic acid-containing products is often effective in preventing recurrence of infection. Acetic acid may be markedly irritating to the ear canal, especially at concentrations of 2% or higher (white vinegar has a concentration of 5%). It has generally been found that boric acid solution, without the presence of acetic acid (Zinc Otic) is effective at managing chronic recurrent yeast otitis and has been demonstrated effective in treatment of mild-to-moderate acute yeast otitis.

Antiinflammatory Therapy

The majority of antimicrobial topical formulations contain antiinflammatory agents (Table 95-4). These aid in decreasing inflammation of the canal associated with the primary ear disease and also reduce inflammation from secondary infections. In some situations products used to clean and treat the ear can have irritant effects, and the addition of glucocorticoids may counteract some of these effects. It is important to remember that the use of products containing more potent steroids such as dexamethasone or betamethasone can suppress the adrenal axis and that animals may exhibit systemic side effects when these are used on a long-term basis. A recently released formulation is a mixture of gentamicin, clotrimazole, and mometasone (Mometamax). Mometasone is a potent topical glucocorticoid, with minimal systemic effects in normal and laboratory animals. It also has longer residual effects, thus allowing for once-daily therapy, and is potentially less of a concern for adrenal axis suppression.

Table 95-1

Cleansers and Drying Agents

Products	Ingredients	Uses/Comments	Manufacturer
Alocetic	Acetic acid Aloe	Maintenance therapy for chronic recurrent otitis	DVM Pharmaceuticals
Bur-Otic	Burrow's solution Acetic acid 1% Hydrocortisone	Antipruritic Antiinflammatory Minor antiyeast and antibacterial effect (acetic acid)	Virbac
Cerulytic	Benzyl alcohol Butylated hydroxytoluene Propylene glycol base	Ceruminolytic: soften otic exudate Indicated in inflamed, highly exudative ear canals Used to loosen exudate before flushing the canal	Virbac
Cerumene	Cerumene (Squalane) 25% in petrolatum base	Ceruminolytic: soften otic exudate Indicated in inflamed, highly exudative ear canals Used to loosen exudate before flushing the canal	EvSCO
Chlorhexiderm flush	2% Chlorhexidine gluconate	Mild cleanser Chlorhexidine can induce topical irritancy Not approved for otic use	DVM Pharmaceuticals
CleaRx cleansing solution Klearwax	Diocetyl sodium Sulfosuccinate 6.5% Urea peroxide 6%	Ceruminolytic: soften and emulsify wax and debris Ideal in highly exudative/proliferative ears without a lot of inflammation	CleaRx: DVM Pharmaceuticals Klearwax: Dermapet
Duoxo micellar solution	Phytosphingosine (0.02%) Polidocanol Rhamnosoft	Recommended for maintenance of seborrheic conditions Micellar solution that enables delivery of phytosphingosine and soothing agents Remove cellular debris and excess sebum Antiinflammatory and antimicrobial properties	Sogeval
Epi-Otic and Epi-Otic Advanced	2.7% Lactic acid 0.1% Salicylic acid Advanced: Antiadhesive Spherulites	Decrease pH of the ear canal (Epi-Otic only; Epi-Otic Advanced is neutral) Effective in maintenance of mild chronic recurrent otitis Advanced formulation has properties to prevent bacterial adherence and deodorizer	Virbac
MalAcetic Otic	2% Acetic acid 2% Boric acid	Effective as maintenance therapy in chronic recurrent yeast otitis	DermaPet
OtiCalm, OtiClens	Benzoic acid Malic acid Salicylic acid	Routine cleansing of mildly exudative ears	OtiCalm: DVM Pharmaceuticals OtiClens: Pfizer Animal Health
OtiFoam	Cocamidopropyl Betaine Salicylic acid Oil of eucalyptus	Breakdown of large debris Can be used in ears with purulent exudate	DVM Pharmaceuticals
OtiRinse	Diocetyl sodium sulfosuccinate (DSS) Salicylic acid Lactic acid Benzoic acid Aloe vera	Routine cleansing of mildly exudative ears Deodorizer	DVM Pharmaceuticals
Otoclean	Salicylic acid (0.23%) Lactic acid Oleic acid Propylene glycol	Markedly ceruminolytic Shown an effective ceruminolytic in in vitro studies	Laboratorios Dr Esteve SA
Zinc Otic	Zinc gluconate Boric acid	Effective as maintenance therapy in chronic recurrent yeast otitis Effective for acute yeast infections	Addison Biological Laboratory, Inc.
Zymox otic	Enzymatic solution with lysozyme, lactoferrin, and lactoperoxidase	Some antibacterial and antiyeast product Can be used as maintenance as well as treatment of dirty "waxy" ears Some practitioners recommend cleaning after Zymox used to break up debris	Leclade, Inc.

Table 95-2

Selected Veterinary Topical Otic Products With Antibacterial Agents

Antibacterial Agent	Uses/Comments	Formulations	Products/Manufacturers
Enrofloxacin	Fluoroquinolone: Bactericidal Gram negative or gram positive bacteria	Emulsion containing silver sulfadiazine	Baytril otic/Bayer
Gentamicin	Aminoglycoside: Bactericidal Gram-negative or gram-positive bacteria	Ointment with betamethasone and clotrimazole Ointment with mometasone and clotrimazole Solution with betamethasone	Otomax/Schering-Plough DVMMax/DVM Pharmaceuticals MalOtic/Vedco Mometamax/Schering-Plough Gentocin Otic/Schering-Plough Aurizon/Vétoquinol
Marbofloxacin	Fluoroquinolone: bactericidal Gram negative or gram positive bacteria	Solution containing clotrimazole and dexamethasone	
Neomycin	Aminoglycoside: bactericidal Similar to gentamicin, but less potent; often chosen for gram-positive bacteria Contact/irritant reactions reported	Ointment with nystatin, thiostrepton, and triamcinolone Solution with thiabendazole and dexamethasone Ointment with isoflupredone acetate and tetracaine hydrochloride	Panalog/Fort Dodge Tritip/Pharmacia Tresaderm/Merial TriTop/Pfizer
Silver sulfadiazine	Structural and metabolic cell disruption Mechanisms not completely understood Broad-spectrum antibacterial and some antiyeast activity	Cream emulsion containing enrofloxacin	Silvadene Cream/Monarch Pharmaceuticals Baytril Otic/Bayer
Tromethamine ethylenediaminetetraacetic (Tris EDTA)	Alkalinizing chelating agent Gram-negative infections Usually used synergistically with other antibiotic	Tris EDTA solution with ketoconazole Tris EDTA solution with chlorhexidine	T8/DVM Pharmaceuticals Triz-EDTA/DermaPet T8 Keto/DVM Pharmaceuticals TrizEDTA Plus/Dermapet

Table 95-3

Selected Veterinary Topical Otic Products With Antifungal Agents

Antifungal Agent	Uses/Comments	Formulation	Products/Manufacturers
Boric acid	Detergent with activity against yeast otic organisms	2% solution containing Zinc 2% solution containing 2% acetic acid	Zinc-Otic/Addison Biological Laboratory, Inc. Malacetic/Dermapet
Clotrimazole	Imidazole antifungal: disrupt ergosterol synthesis Mild-to-moderate potency against <i>M. pachydermatis</i>	Ointment containing gentamicin and betamethasone Ointment containing marbofloxacin and dexamethasone	Otomax/Schering-Plough; DVMMax/DVM Pharmaceuticals; MalOtic/Vedco Aurizon/Vétoquinol
Ketoconazole	Imidazole antifungal: disrupts ergosterol synthesis	Solution containing Tris-EDTA 2% Cream	T8 Keto/DVM Pharmaceuticals Ketoconazole Cream/Taro Pharmaceuticals
Miconazole	Imidazole antifungal: disrupts ergosterol synthesis	1% Lotion or 2% cream Solution with chlorhexidine gluconate	Conofite/Schering-Plough Malaseb Flush/DVM Pharmaceuticals
Nystatin	Polyene antifungal: binds sterols in the fungal cell membrane Relatively weak activity against <i>Malassezia pachydermatis</i>	Ointment with neomycin, thiostrepton, and triamcinolone	Panalog/Fort Dodge
Terbinafine	Allylamine antifungal: inhibition of squalene epoxidase	Various 1% over-the-counter preparations	Lamisil/Novartis
Thiabendazole	Benzimidazole antifungal: disrupts ergosterol synthesis	Solution with neomycin and dexamethasone	Tresaderm/Merial

Table 95-4

Antiinflammatory Agents Available in Topical Products

Antiinflammatory Agent	Uses/Comments	Formulations	Products/Manufacturers
Betamethasone	25 times as potent as HC Even short-term use can result in suppression of the adrenal axis and systemic effects	Ointment with gentamicin and clotrimazole Solution with gentamicin	Otomax /Schering-Plough; DVMMax/DVM Pharmaceuticals; MalOtic/Vedco Gentocin Otic/Schering-Plough
Dexamethasone	25 times as potent as HC Even short-term use can result in suppression of the adrenal axis and systemic effects	Solution with neomycin and thiabendazole Ointment with marbofloxacin and clotrimazole	Tresaderm/Merial Aurizone/Vétoquinol
Dimethyl sulfoxide (DMSO)	Nonsteroidal antiinflammatory Possible reduction in fibroplasia	Solution with fluocinolone	Synotic/Fort-Dodge
Fluocinolone	100 times as potent as HC Even short-term use can result in suppression of the adrenal axis and systemic effects	Solution with DMSO (which will add to systemic absorption)	Synotic/Fort Dodge
Hydrocortisone (HC)	Mild steroidal antiinflammatory Use in mild chronic recurrent ceruminous otitis	Solution with Burrow's solution and acetic acid Solution with 2.5% acetic acid and 2% colloidal sulfur Enzymatic solution containing HC Solution with 2% acetic acid and 2% boric acid Lotion (not approved for otic use)	BurOtic/Virbac CleaRx Drying Agent/DVM Pharmaceuticals Zymox Otic/Laclede, Inc. Malacetic HC/DermaPet CortiCalm Lotion/DVM Pharmaceuticals
Mometasone	25 times as potent as HC Negligible systemic bioavailability, minimal systemic adverse effects	Ointment with gentamicin and clotrimazole Numerous human inhaled and topical products	Mometamax/Schering-Plough Nasonex/Schering-Plough; Elocon Cream/Schering-Plough
Triamcinolone	Five times as potent as HC	Ointment containing nystatin, neomycin, and thioestrepton	Panalogue/Fort Dodge

Products containing hydrocortisone can potentially be used for chronic recurrent otitis secondary to mild allergies. However several of these products contain ingredients that are irritating, which can negate the mild antiinflammatory effect of hydrocortisone. Maintenance hydrocortisone products need to be selected on a case-by-case basis, depending on how effective they are in controlling the inflammation from the primary disease, usually allergic. They are not very beneficial in acute, exudative, or proliferative otitis.

Topical Ototoxicity

Patients with otitis commonly present with ruptured tympanic membranes. Certain formulations contain ingredients that have been shown to be ototoxic and are contraindicated when a ruptured tympanum is present. Ototoxicity is defined as the tendency of certain therapeutic agents to cause functional impairment and cellular

degeneration of the inner ear and the eighth cranial nerve. It may be reversible or irreversible. Ototoxicity is differentiated from neurotoxicity, in which the site of action is central to the eighth cranial nerve. Most notable of the ototoxic drugs are the aminoglycoside antibiotics (especially gentamicin), but other numerous known ototoxic agents are listed below (Box 95-1). Products such as acetic acid that are not ototoxic but are irritating can also be a concern. At times culture and sensitivity testing directs clinicians to use ototoxic antibiotics if other options are not available. Dermatologists may recommend these products in resistant cases; however, the client must be informed of the risks and benefits of pursuing this therapy.

MAINTENANCE OF CHRONIC RECURRENT CONDITIONS

Cases of chronic, recurrent otitis are usually secondary to an inadequately controlled primary condition, permanent

Box 95-1

List of Known Ototoxic Substances

Antibiotics**Aminoglycoside antibiotics**

Streptomycin
Dihydrostreptomycin
Kanamycin
Gentamicin
Neomycin
Tobramycin
Netilmicin
Amikacin

Macrolide antibiotics

Erythromycin
Clindamycin
Azithromycin

Miscellaneous Drugs**Salicylates**

Acetylsalicylic acid (aspirin)
Nicotine
Quinine
Loop diuretics
Furosemide
Ethacrynic acid
Bumetanide

Platinum-based antineoplastic agents

Carboplatin

Xylene

damage to the ear canal, or undiagnosed/uncontrolled otitis media. Changes to the canal from chronic recurrent disease can destroy the physical and immunologic mechanisms of the ear canal that keep it free of pathogens and debris. This makes the ear even more susceptible to recurrent infections. Table 95-1 gives a list of products frequently used by veterinarians; however, scores of products are available over the counter through pet stores and on the Internet. It is important to know which products are being applied into the patient's ears and to understand their possible effects.

Maintenance therapy has the following goals:

1. To keep the ear clean and free of excess wax and ceruminous debris. This is achieved with cleaning and sometimes antiinflammatory agents that decrease excessive wax and cerumen production.
2. To decrease inflammation and pruritus, thus avoiding self-trauma and discomfort. This is achieved by addressing the primary disease and providing antiinflammatory therapy and/or by achieving the other goals listed and thus decreasing the inflammation.
3. To decrease the number of infectious organisms in the canal and maintain an "unfriendly" environment for their growth, by either decreasing the canal pH or adding detergents or other products that interfere with microorganism metabolism and growth.

4. To provide therapy that promotes regulation of epithelialization and wound healing. For example, products such as Aloetic or Otrine contain aloe to help soothe and maintain the moisture barrier of the ear canal. Another product, Duoxo micellar solution contains phytosphingosine and other products to decrease excessive buildup in seborrheic conditions. In addition, Zinc Otic contains zinc gluconate with the goal of promoting normalization of canal epithelium and wound healing.

Systemic Therapy for Otitis Externa and Media

LYNETTE K. COLE, *Columbus, Ohio*

Otitis externa is defined as inflammation of the external ear canal that may also involve the pinna. It is the most common disease of the external ear canal of the dog and cat. The reported prevalence in the dog ranges from 10% to 20% of the population; in the cat otitis externa is less common, ranging from 2% to 10%, and is usually caused by a parasitic etiology.

ETIOLOGIES OF OTITIS EXTERNA

The etiologies of otitis externa may be broken down into predisposing factors, primary causes, and perpetuating factors. If these factors and causes are not diagnosed, treated, and controlled, the otitis externa may become chronic and recurrent. Predisposing factors alone do not cause the otitis externa, but they increase the risk of development of the disease. These predisposing factors include otic conformation (stenotic canals, hair in canal, pendulous pinnae) excessive moisture (swimmer's ear), and treatment effects (trauma from cotton-tipped applicators, irritant topical solution, inappropriate use of combination topical therapy). Primary causes directly cause the otitis externa and include parasites (*Otodectes cynotis*, demodicosis, *Otobius megnini*), hypersensitivity disorders (atopic dermatitis, cutaneous adverse food reaction, allergic contact dermatitis), keratinization disorders (primary idiopathic seborrhea, hypothyroidism), neoplasms, polyps, and autoimmune diseases. Perpetuating factors are factors that prevent the resolution of the otitis externa and include bacteria, yeast, otitis media, and progressive pathologic changes.

OTITIS MEDIA

Otitis media is defined as inflammation of the middle ear cavity. The most common cause of otitis media is an extension of an infectious otitis externa into the middle ear cavity through a ruptured tympanic membrane. In dogs otitis media occurs in 16% of acute otitis cases, whereas in cases of chronic otitis externa 50% to 89% may have concurrent otitis media. An intact tympanic membrane does not rule out otitis media because the defect may heal over the infection.

MANAGEMENT OF OTITIS

Goals of Medical Management of Otitis

The goals of medical management of otitis externa and otitis media are to reduce inflammation and resolve

infection. Successful long-term medical management of otitis externa and otitis media requires identification and control of the primary underlying disease and the predisposing and perpetuating factors. Topical therapy is recommended for all cases of otitis externa and otitis media and may include ear cleaning and drying agents, glucocorticoids, antibiotics, antifungals, or antiparasitics (see Chapter 95). Systemic therapies used for medical management of otitis externa and otitis media are similar and include glucocorticoids, antibiotics, antifungals, and antiparasitics. However, systemic therapy is not always required in the management of otitis.

Systemic Glucocorticoids

Systemic glucocorticoids are used to help alleviate the pain and inflammation associated with otitis externa. Glucocorticoids are antipruritic, antiinflammatory, and antiproliferative and decrease sebaceous and apocrine secretions in the ear. In addition, in patients with severe hyperplasia and stenosis of the ear canal, systemic glucocorticoids are warranted to reduce the inflammation to allow examination of the ear and otic flushing if required. If on reevaluation the hyperplasia and stenosis have not decreased to allow the otic examination, surgical management of the otitis may be indicated. Short-acting systemic glucocorticoids such as prednisone or prednisolone are administered orally at 0.05 to 1 mg/kg every 24 hours for up to 14 days. This treatment course may be extended if initial improvement is noted, but moderate proliferation of the ear canal is still present. The dosage remains the same, but the frequency is tapered to every other day. In cases with marked hyperplasia and stenosis, initial doses up to 2 mg/kg every 24 hours for the first 3 to 5 days, reduced to 1 mg/kg every 24 hours, may be required.

When there is only vertical ear canal stenosis, intral-
esional triamcinolone acetonide (Vetalog) may be effective. It is injected using a spinal needle or 25-gauge needle in a ring pattern around the vertical ear canal, injecting approximately three or four locations with a total dose of no more than 0.1 mg/kg. Short-term side effects of glucocorticoids include polyuria, polydipsia, polyphagia, and panting. Longer use of glucocorticoids may induce additional side effects such as iatrogenic hyperadrenocorticism, steroid hepatopathy, gastric ulcers, alopecia, cutaneous atrophy, hypertension, demodicosis, and urinary tract infections.

Systemic Antimicrobial Therapy

Indications for Systemic Treatment of Bacterial Otitis

Systemic antimicrobial therapy for infectious otitis externa and otitis media is controversial. In dogs with end-stage otitis externa and concurrent otitis media, bacterial organisms may be isolated from the exudate in the lumen of the vertical ear canal (Cole et al., 2005a) and middle ear cavity (Cole et al., 2005b), as well as from the tissue from these sites. Therefore most agree that systemic antibiotics are indicated in patients with otitis media, with severe proliferative chronic otitis externa, with ulcerative otitis externa, when inflammatory cells are seen cytologically (indicating deeper skin involvement), and when owners cannot administer topical therapy. The selection of a systemic antimicrobial agent must be made based on culture and susceptibility (C/S) testing from the external ear (for otitis externa) and middle ear (for otitis media). However, therapy may be initiated based on cytologic results while awaiting the C/S results.

Systemic Therapy for Staphylococcal Otitis

The most common coccoid bacteria isolated from dogs with otitis externa or otitis media is *Staphylococcus intermedius*. Good empiric choices while waiting on C/S results include cephalexin (22 mg/kg q12h, orally [PO]) or amoxicillin trihydrate-clavulanate potassium (Clavamox, Pfizer Animal Health, 13.75 to 22 mg/kg q12h, PO).

Systemic Therapy for *Pseudomonas* Otitis

Probably the most challenging bacterial otic infections are those infected with *Pseudomonas aeruginosa* (Table 96-1). Systemic treatment options may be limited because of antibiotic resistance. At the present time the fluoroquinolones are the only oral systemic antibiotic available for the treatment of *P. aeruginosa*. Most veterinary dermatologists recommend starting an oral fluoroquinolone while waiting on the C/S results. When using the fluoroquinolones in the dog, the upper end of the dose should be administered. Rare reports of blindness caused by retinal degeneration have been reported in cats administered enrofloxacin; therefore the low end of the dose of an oral fluoroquinolone should be administered in the cat.

In multidrug-resistant *P. aeruginosa* infections, systemic β -lactam antibiotics such as ticarcillin disodium-clavulanate potassium (Timentin, GlaxoSmithKline), imipenem (Primaxin, Merck), meropenem (Merrem, AstraZeneca LP), and ceftazidime sodium (Fortaz, GlaxoSmithKline) may be options but are very expensive, must be administered parenterally, and should only be considered after topical cleaning and antimicrobial agents have been ineffective. A potential side effect of imipenem and meropenem is seizures, and they should be used cautiously in patients prone to seizure disorders.

Aminoglycoside antibiotics such as gentamicin and amikacin are less commonly prescribed but remain potentially efficacious drugs for the treatment of *P. aeruginosa*

Table 96-1

Systemic Drugs and Suggested Dosages for the Treatment of *Pseudomonas Aeruginosa* Otitis Externa/Otitis Media

Drug Name (Trade Name)	Dosage
Fluoroquinolone Antibiotics	
Marbofloxacin (Zeniquin, Pfizer Animal Health)	Dog: 5.5 mg/kg q24h, PO Cat: 2.75 mg/kg q24h, PO
Enrofloxacin (Baytril, Bayer Animal Health)	Dog: 20 mg/kg, q24h, PO Cat: 5 mg/kg q24h, PO
Ciprofloxacin	Dog: 20 mg/kg q24h, PO
β-Lactam Antibiotics	
Ticarcillin disodium-clavulanate potassium (Timentin, GlaxoSmithKline)	Dog: 15 to 25 mg/kg q8h, IV
Imipenem (Primaxin, Merck & Co)	Dog and cat: 10 mg/kg q8h, diluted in 100 ml suitable IV solution, administered IV over 30 to 60 minutes
Meropenem (Merrem, AstraZeneca LP)	Dog: 12 mg/kg q8h, SQ or 24 mg/kg q8h, IV
Ceftazidime sodium (Fortaz, GlaxoSmithKline)	Dog and cat: 30 mg/kg q6h, IV, IM Dogs only: 30 mg/kg q4h, SQ Dogs only: Constant IV infusion: loading dose of 4.4 mg/kg, followed by 4.1 mg/kg/hr, delivered in IV fluids
Aminoglycoside Antibiotics	
Gentamicin	Dog: 10 to 14 mg/kg q24h, IM, SQ, IV Cat: 5 to 8 mg/kg q24h, IM, SQ, IV
Amikacin	Dog: 15 to 30 mg/kg q24h, IM, SQ, IV Cat: 10 to 15 mg/kg q24h, IM, SQ, IV

otic infections. These drugs are also administered parenterally and have the potential for nephrotoxicity. Animals must be monitored with periodic urinalysis for increased protein or tubular casts and serum blood urea analysis and creatinine.

Indications for Systemic Treatment of Yeast Otitis

Indications for systemic antifungal agents are similar to those mentioned previously for bacterial infections and include patients with yeast otitis media, patients with severe yeast otitis externa, or owners who cannot administer topical therapy. In one study neither pulse-dose or daily-dose itraconazole alone significantly decreased yeast organisms identified cytologically from otic exudate in dogs with yeast otitis externa, suggesting that otic yeast infections may require topical therapy in addition to systemic therapy for resolution (Pinchbeck et al., 2002). Both ketoconazole (5 mg/kg q24h) and itraconazole ([Sporanox, Janssen Pharmaceutica Products, LP], 5 mg/kg PO q24h or pulse-dosed 2 days on and 5 days off) have been used in

dogs, whereas itraconazole (5 mg/kg PO q24h) is recommended for use in the cat.

Systemic Antiparasiticide Therapy

Treatment of *O. cynotis* in the dog or cat requires treatment of all in contact animals, as well as the affected animal. Selamectin (Revolution, Pfizer Animal Health) is a semisynthetic avermectin topical endectocide approved by the Food and Drug Administration for the treatment of *O. cynotis* in the dog and cat (two treatments at 30-day intervals). Even though selamectin is applied topically to the skin, it is quickly absorbed into the bloodstream, forming reservoirs in the sebaceous glands. Ivermectin (0.2 to 0.3 mg/kg q2weeks, subcutaneously for three treatments) is effective against *O. cynotis* in the dog and cat. Side effects from ivermectin may include ataxia, hypermetria, disorientation, hyperesthesia, tremors, hyperreflexia, mydriasis, hypersalivation, depression, blindness, coma, and death. Nonspecific signs include vomiting, diarrhea, and anorexia. Ivermectin should not be administered to collies and collie-crosses, Australian shepherds, Shetland sheepdogs, Old English sheepdogs, English shepherds, long-haired whippets, and silken windhounds due to profound adverse reactions or to heartworm-positive dogs. The use of ivermectin for the treatment of *O. cynotis* is off label; therefore a consent form should be signed by the owner before administration.

CHAPTER 97

Ear-Flushing Techniques

DAWN LOGAS, Maitland, Florida

EAR FLUSHING

The most important first step in the management of any case of otitis is to properly clean the external ear canal and flush the middle ear cavity if the tympanum is absent or diseased. The procedure should be performed at the initial visit after obtaining cytologic specimens and possibly a specimen for culture from the diseased ear. In mild cases of otitis, ear flushing may be performed with gentle restraint, but in most cases the ears are painful enough to warrant heavy sedation with propofol (Diprivan 1%, Zeneca) or ketamine and diazepam. In more severe cases of otitis externa and in most cases of otitis media, general anesthesia is necessary.

In some of the most severe cases, in which the canals are extremely inflamed and swollen, systemic and topical therapy is initiated first, and a 3- to 14-day delay is necessary before cleaning. This allows the canal to open and the tympanic membrane to be visualized more easily.

The flushing solution used depends on the degree of inflammation, the characteristics of the discharge, and the status of the tympanic membrane. Commonly used solutions are dioctyl sodium sulfosuccinate (DSS), CLEAR_x ear cleansing solution (DVM Pharmaceuticals), or squalane (Cerumene, Evsco Pharmaceuticals) for waxy discharges; and Epi-Otic (Allerderm/Virbac), tromethamine ethylenediaminetetraacetic (Tris EDTA), 0.05%

to 0.2% chlorhexidine solutions, and 2.5% acetic acid (50:50 vinegar:water) or saline for purulent discharges. All of these solutions except saline have the potential to damage exposed middle-ear structures, although the caseous or purulent material being removed from the middle ear probably poses a greater threat. When the tympanum is known to be absent, a gentle solution such as 2.5% acetic acid or saline should be used if possible. Unfortunately many times these solutions alone do not remove the debris, and a more caustic cleaning solution must be used. At the end of the procedure it is important to flush the caustic solution out of the canal and middle ear completely with water or saline to minimize any damage the solution may cause.

In-Office Ear Flushing

A bulb syringe (Daval, Inc.) or a No. 3 to No. 12 Fr red rubber feeding tube attached to a 6- to 12-ml syringe is an excellent and relatively safe flushing apparatus for in-office use. The wide end of the tube must be trimmed to accommodate the syringe hub. The tip is then cut off the other end so the final length of the tube is 4 to 6 inches or one to two times the length of the ear canal. Both straight and curved dull buck ear curettes (Edward Week & Co) can be used to remove large pieces of wax and debris. Once the horizontal canal has been cleared, it is usually easier to assess the status of the tympanic membrane. In many cases of chronic otitis, the tympanum is still difficult to visualize because the canal is stenotic secondary to lichenification and fibrosis. If the tympanum cannot be visualized, its status can be assessed indirectly by observing the curette catching on any bony prominence, the tube tip disappearing from view, the use of excessive tubing and fluid in the canal, or the act of the patient swallowing after infusion of fluid. Any of these observations would indicate a false middle ear or imperforate tympanum. If the tympanum is visually intact but this is a case of chronic otitis (>3 months' duration), a myringotomy using a dull buck curette may be necessary. A culture should always be taken from the middle ear if there is any evidence of fluid behind the membrane or if there is membrane opacity and fibrosis.

The hazards of deep ear cleaning include inadvertent rupture of the tympanum, vestibular dysfunction, auditory dysfunction, contact irritant and allergy, and introduction of other pathogens. The most common hazard is the potential rupture of the tympanic membrane. A normal tympanum is difficult to rupture; therefore, if the membrane ruptures with gentle manipulation, it was probably weakened and diseased. The occurrence of vestibular auditory dysfunction is unpredictable. In the dog it is uncommon, usually mild, and most of the time lasts only a few hours to a couple of days. It occurs more frequently in the cat, and the signs are usually more pronounced and may be permanent. To avoid contact irritation, a gentle solution should be used whenever possible, or more caustic solutions must be rinsed out extremely well with water or saline. New pathogens can also be introduced into an already inflamed ear via unsterilized ear-cleaning equipment. Bulb syringes and

feeding tubes should not be used for multiple patients. It is difficult to completely sterilize the rubber; therefore resistant strains of *Pseudomonas*, *Escherichia coli*, and *Proteus* can propagate.

At-Home Ear Flushing

Once the ear has been cleaned in the office, a home treatment plan for the owners must be designed according to the organism or organisms found on cytologic studies or culture, the chronicity of the ear disease, and the presence of a tympanum. In many cases a prepared solution in a squeeze bottle is all that is necessary. If there is a great deal of purulent material, a bulb syringe should be used, and the owners instructed in its appropriate use. After each use the bulb syringe should be rinsed out several times with 50:50 vinegar with isopropyl alcohol to minimize bacterial overgrowth in the bulb. The bulb syringe should be changed every 2 to 5 weeks, depending on the severity of the infection.

In the case of severe otitis or in a fractious patient, a flushing device may temporarily be affixed to the animal. Heavy sedation or general anesthesia should be used. The open end of a red rubber feeding tube is secured via sutures or glue to the dorsal skin of the neck and head. The tube is then placed into the ear canal rostrally through the area of the pretragic incisure and secured in place with glue or suture. The tip of the tube should be trimmed so that the end of the tube is one half to three quarters of the way down the horizontal canal but not touching the tympanum or the middle-ear cavity. The tube should be approximately one-half to three-fourths the diameter of the horizontal canal. This helps minimize tube movement and subsequently patient discomfort. There should be enough space around the tube for fluid to backwash out of the ear during flushing. This will prevent a buildup of water pressure and possible middle ear and vestibular damage. The tube usually remains in place for 5 to 10 days, but it can remain in place longer if needed. There should be an Elizabethan collar on the dog at all times. Owners should be instructed to flush the cleaning solution (i.e., chlorhexidine solution (0.05% to 0.2%), saline, or 50:50 vinegar with water) through the tube gently with a 6- to 12-ml syringe. Each time the canal is flushed, a total volume of 10 to 15 ml should be instilled. As much of the fluid as possible should be evacuated from the ear canal after each infusion. The ear should be flushed once to three times daily, depending on the severity of the infection. Antibiotic solutions can also be instilled into the horizontal canal through this apparatus by infusing 0.5 to 1 ml of medication into the tube and then flushing the medication through the tube into the canal using air.

The type of solution and frequency of flushing prescribed for home care depend on the severity of infection, consistency of the discharge, chronicity of the otitis, presence of yeast or bacteria, and presence or absence of a tympanum. For bacterial infections chlorhexidine solution (0.05 to 0.2%) and saline are good, gentle flushes. For *Pseudomonas aeruginosa* infections, a 5- to 10-minute contact time with Tris-EDTA, 50:50 vinegar:water or otic Domeboro solution (Bayer Pharmaceutical) is a better

choice because these agents have bactericidal activity against *Pseudomonas*. It is important to remember that purulent discharge inactivates many topical antibiotics; accordingly the ear should be flushed before each application of antibiotic until the ear is producing little-to-no purulent material. Initially the frequency of flushing for severe cases, especially resistant *Pseudomonas* infections, can be three to four times daily. In most cases of less severe otitis, twice daily suffices. As therapy continues, the frequency should decrease to several times per week and then once weekly to every other week prophylactically.

As with bacterial otitis, flushing ears can be important in the treatment of yeast otitis. Flushing helps to remove the waxy organism-filled debris, acidify, and then dry the horizontal canal, making the microenvironment of the canal unsuitable for yeast growth. The frequency of application again depends on the severity of otitis and the chronicity of the disease. In severe cases flushing may be one to two times daily but should quickly drop to two to three times weekly. Over time it drops further to a maintenance level of once weekly to once every other week. The agents most commonly used are Epi-Otic, DSS, and 50:50 vinegar with alcohol.

It is particularly important that dogs with chronic histopathologic ear canal changes such as fibrosis, stenosis, and lichenification be placed on a maintenance flushing program. Ears with chronic changes usually have increased cerumen production, hyperplasia of the stratum corneum, and decreased epidermal migration

(self-cleaning). This leads to an increased buildup of debris in the canal. Flushing the ears helps to remove the debris and acidify the canal, which helps prevent recurrence of active infections. The frequency of flushing ranges from two to three times weekly to once every other week. The solutions commonly used are Epi-Otic, chlorhexidine flush, Otic Domeboro, and vinegar with alcohol or water (50:50).

Although flushing is extremely important in the management of both chronic and acute otitis, it is imperative that the clinician remember that flushing too vigorously and too frequently can also be detrimental to the otic epidermis. The animal with severe otitis undergoing flushing numerous times per day should be checked frequently, and flushing should be varied, depending on the cytologic and otic examination. This prevents the ear flushes from doing more harm than good.

CHAPTER 98

Feline Demodicosis

KARIN M. BEALE, *Houston, Texas*

DANIEL O. MORRIS, *Philadelphia, Pennsylvania*

Feline demodicosis is considered a relatively “rare” parasitism; however, in certain regions this condition is endemic and is not uncommon. When compared to canine demodicosis, little is known about feline demodicosis. Infected cats may present with a wide variety of clinical signs and should be considered in the differential diagnosis of many feline skin disorders. Two species of mites have been recognized to cause feline skin disease.

DEMODEX GATOI

Clinical Signs and Differential Diagnosis

Demodex gato is a short, broad mite that inhabits the stratum corneum (the most superficial layer) of the epidermis. The mite is similar in appearance to *Demodex criceti*, the superficial dwelling mite causing skin disease in hamsters. The primary clinical sign resulting from infection

with this mite is pruritus, and the intensity of the pruritus is suggestive of a hypersensitivity response. The most common clinical presentation is self-inflicted alopecia caused by overgrooming. The alopecia is often symmetric in nature and is typically quite extensive. Most commonly the ventral abdomen, flanks, and anterior forelimbs are affected. This is more likely because these areas are most easily reached with grooming rather than being related to areas most inhabited by the mites. Other clinical signs typical of the cutaneous reaction patterns most commonly associated with feline allergic dermatoses may be present: miliary dermatitis and the eosinophilic dermatitis complex (i.e., eosinophilic plaques, indolent lip ulcers, and eosinophilic granulomas).

Occult cases of *D. gatoi*, appear to be common. This is similar to canine scabies and further supports the presence of a hypersensitivity component. The scarcity of mites on many pruritic cats with *D. gatoi* can easily lead to a missed diagnosis (see following paragraphs). It is suspected that affected cats are physically removing the mites (by licking), making the mites difficult or impossible to find with routine skin scrapings. The difficulty in finding these mites with skin scrapings and the ease with which they can be overlooked is another important factor that can contribute to misdiagnoses.

It is very important to note that some infested cats demonstrate no clinical signs whatsoever, further supporting the possibility that the pruritus induced in affected cats may be associated with a hypersensitivity response to the parasite. In a multiple-cat household there may be a combination of cats demonstrating clinical signs and cats that are asymptomatic. The feline housemates of affected cats should always be screened for parasitism. The distribution pattern of clinical signs is variable, but most commonly the ventral abdominal and flank regions are affected. However, facial and acral lesions may also occur, as can otitis externa. The pattern of lesions may be a reflection more of areas that cats typically groom rather than the distribution of mites. The differential diagnosis for a cat presenting with the pattern of self-induced alopecia should include flea-allergic dermatitis, atopic dermatitis, adverse food reaction, Cheyletiellosis, *Otodectes cynotis*, and psychogenic alopecia; in the case of miliary or plaque lesions, dermatophytosis, pyoderma, and cutaneous neoplasia should be considered.

Transmission

A unique feature of *D. gatoi* infestation when compared to canine demodicosis is an apparent risk for contagion among cats via casual contact. Fomite transmission may occur as well. Most infested cats have a history of going outdoors, being boarded, or possibly having been adopted from a shelter. This is the only *Demodex* species of domestic mammals for which horizontal transmission through casual contact has been reported.

Pathogenesis

The pathophysiology of *D. gatoi* infestation is not well known. Some cases reported in the literature have had histories of glucocorticoid therapy, although it is unclear

whether this is truly a risk factor for the development of disease. It is more likely that the cats were treated with glucocorticoids for the pruritus induced by the mite. Other sources of systemic or localized immunosuppression have been reported in conjunction with *D. gatoi* infestation, including retroviral infection, diabetes mellitus, and cancer chemotherapy. We have diagnosed *D. gatoi* infestation in cats that have no history of glucocorticoid therapy and no associated systemic disease. Cats often have a history of roaming or exposure to other cats. Introduction of an asymptomatic infected cat from a shelter to a household with other cats may lead to disease in previously unaffected cats.

It is unknown if *D. gatoi* is part of the normal microfauna of feline skin, but our suspicion is that it is not. There appears to be marked regional variability in the distribution of this parasite since the condition is commonly diagnosed in the Gulf Coast region of the United States and is less commonly reported in other areas.

DEMODEX CATI

Clinical Signs and Differential Diagnosis

Demodex cati is a long, slender mite that has a similar morphology to *Demodex canis*. Like *D. canis*, the habitat of *D. cati* is the hair follicle and sebaceous glands/ducts. The presence of the mite provokes follicular inflammation, leading to a combination of alopecia, follicular plugging (comedones), papules, pustules, scale, crusts, and even erosion/ulceration. The distribution of skin lesions is variable, but most commonly lesions are focal and involve the head/face and distal limbs. Generalized demodicosis with *D. cati* is uncommon. The mite may also inhabit the external ear canals, leading to a ceruminous otitis externa, which is variably pruritic. Otitis may be the only manifestation of disease or may be seen concurrently with skin disease.

Differentials for *D. cati* infestation include dermatophytosis, pemphigus foliaceus, bacterial folliculitis, *Notoedres cati* (feline sarcoptic mange), *O. cynotis* (ear mites), and bacterial and yeast otitis externa. Pruritus is commonly seen with infection; therefore allergic dermatitis (atopy, food allergy/intolerance, and flea allergy) would be differentials in the pruritic cat.

Pathophysiology

The mite is considered part of the naturally occurring microfauna of feline skin, and mite reproduction to the point of causing dermatitis may be associated with an underlying systemic disease (retroviral infection, diabetes mellitus, neoplasia) or iatrogenic immunosuppression (glucocorticoids, cancer chemotherapy). Localized immunosuppression (caused by squamous cell carcinoma in situ) has also been implicated as a predisposing cause. Some patients with *D. cati* infestations have no apparent underlying disease or predisposing drug use; therefore alterations in immune response may not be a prerequisite for developing disease. Studies evaluating the cell-mediated and humoral immune responses of cats to *D. cati* have not been performed.

Diagnosis of Demodicosis

The diagnosis of *D. cati* is usually straightforward since mites are typically found with scrapings. Since they reside in hair follicles, deep/concentrated scrapings (such as one might perform for canine *Demodex*) are necessary. The skin should be squeezed gently to express mites toward the surface in-between cycles of scraping, until a generous amount of blood and debris is collected. For areas more difficult to scrape (such as eyelids, toes, and interdigital spaces) evaluating trichograms may be useful since mites may be dislodged along with the hairs. In heavily crusted or ulcerated areas, skin biopsy may reveal the diagnosis and help rule out other differentials. In rare cases low numbers of mites can make diagnosis more difficult. Although *D. cati* is part of the normal cutaneous microfauna, even a single mite should be considered suspicious when collected from a compatible skin lesion. If no other explanation for the lesion is found, treatment should be instituted on a trial basis.

In cases involving *D. gatoi*, in which occult infestation is common, a single mite found from the composite of multiple scrapings is diagnostic. A scraping technique similar to that used for scabies is appropriate: broad, superficial scrapings of large surface areas. Areas that are not easily reached with grooming (i.e., dorsal neck, thorax) may be more likely to produce positive results since the mites can't be physically removed from these areas. Negative findings on scrapings can't be relied on to rule out this condition. This is particularly true in endemic areas. Alternative measures include fecal flotation (as pruritic cats appear to groom away and ingest the mites) and therapeutic trials (see following paragraphs). The mites may also be found on occasion using cellophane tape to collect samples from the surface of the skin. It is strongly recommended that all in-contact cats be screened for infestation since some asymptomatic cats may have positive results on skin scrapings.

Regardless of the mite species involved, cats with demodicosis should be screened for retroviral diseases (leukemia and immunodeficiency viruses) and for other systemic diseases if indicated by clinical signs. For pruritic cats that have previously received glucocorticoid therapy, a final diagnosis must be reserved until miticidal treatment is finished because some may have another primary pruritic dermatosis.

Treatment

The recommended treatment for infested cats is a series of six lime sulfur dips performed at weekly intervals. A concentration of 2% is effective, but failures with 1% solutions have been documented. The hair coat should be totally saturated, and cats should "soak" in the lime sulfur for a minimum of 5 minutes. The topical solution should not be rinsed off, and the cats should be allowed to air dry. An Elizabethan collar is recommended to prevent ingestion of the dip while drying. Lime sulfur causes a temporary discoloration of light-colored fur and is extremely malodorous while wet. Persons using the solution should be advised that it tarnishes jewelry. Cats typically demonstrate significant clinical improvement after

three treatments; however, mites may still be found with skin scrapings at that time. After the third dip some cats may experience an increase in scaling and pruritus, which is most likely caused by the drying (or potentially irritating) effects of the dip itself. This usually resolves rapidly after dipping is discontinued.

Cats with negative findings on skin scrapings that have symmetric alopecia and are on appropriate flea control may have an occult infestation with *D. gatoi*. A therapeutic trial with three lime sulfur dips is recommended. If the cat demonstrates improvement after the third dip, a full series of six dips is recommended, and other household cats should be dipped as well. If the cat is not better by the third week, it is unlikely that the pruritus is caused by demodicosis.

Because of the aesthetically unappealing nature of lime sulfur dips, many owners are reluctant to use this treatment, and other options have been used. Treatment with once-weekly ivermectin has been ineffective for both species of mites. Treatment with topical selamectin on a weekly basis has also been ineffective. Once-daily or every-other-day ivermectin at 300mcg/kg is effective in treating both species of mites. For *D. cati* treatment should be continued until negative scrapings are obtained. For *D. gatoi* infestation, we recommend treatment for 2 weeks past resolution of clinical signs with a minimum of 6 weeks of treatment. Because of the potential for toxicity with ivermectin (including Heinz body anemia resulting from the propylene glycol vehicle), lime sulfur is preferred over daily or every-other-day ivermectin treatment.

Treatment of all cats in a household with an infected or potentially infected cat is recommended. In the case in which occult demodicosis is suspected in one cat and the owner is reluctant to treat all cats, the potentially infested individual should be isolated during the treatment period. If the cat improves with treatment, all the other cats in the household should be treated as well. If the owner is unwilling to treat all household cats, he or she should be aware that there is the possibility of reinfestation when treatment is stopped if the other cats happen to be harboring an occult infestation.

Feline Viral Skin Disease

RUDAYNA GHUBASH, *Marina del Rey, California*

FELINE HERPESVIRUS-1

Feline herpesvirus-1, a virus in the Herpesviridae family, is a common cause of respiratory illness, conjunctivitis, stomatitis, and corneal ulceration in feline patients. The majority of cats who contract this virus become asymptomatic carriers that harbor the virus in the trigeminal ganglia. Symptoms commonly recur when these animals experience stress such as moving, entering multicat households, boarding, pregnancy, surgery, or receiving glucocorticoids. In the cases reported in the literature, there has not been a causal link between this condition and animals with feline leukemia virus (FeLV) or feline immunodeficiency virus (FIV).

It has been demonstrated that this virus can manifest itself with dermatologic lesions in the absence of concurrent ophthalmic or respiratory symptoms in domestic cats and in cheetahs. There does not appear to be an age, breed, or sex predilection. Skin lesions typically follow the path of the trigeminal nerve on the haired surface of the face and nasal planum, although the ears, feet and ventrum can also be affected. The lesions are characterized by an ulcerative, erosive crusting dermatitis that can also display marked erythema and swelling. Because of shedding of the virus, skin lesions are often noticed to be associated in the location of lacrimal and salivary secretions. Feline herpesvirus can also be an underlying trigger of erythema multiforme in the cat with the absence of the ulcerative, erosive lesions described here.

Differential diagnoses of this condition include allergic disease, mosquito bite hypersensitivity, squamous cell carcinoma, eosinophilic granulomas complex lesions, pemphigus foliaceus, and idiopathic ulcerative dermatitis of Persian cats.

Diagnosis of this condition is made with a combination of *histopathology and polymerase chain reaction (PCR) of skin* samples. Histopathology is characterized by necrosis and ulceration of the epidermis extending into the dermis. Hair follicles and the perivascular dermis are usually inundated with a mixed inflammatory cell dermatitis, with a significant eosinophilia. Although they can be difficult to find, intranuclear viral inclusions in the superficial and follicular epithelium can be appreciated. Immunohistochemistry and PCR can be done to confirm these inclusions as herpesvirus-1 inclusion bodies. Even if intranuclear inclusion bodies are not appreciated, PCR and immunohistochemistry can be used to detect feline herpesvirus in tissue, with PCR considered the more sensitive test. It is not useful to run PCR on serum or mucocutaneous samples alone, since many cats have been exposed to the virus and a

positive result on serum may be an incidental finding and not confirmation of a diagnosis. Many diagnostic laboratories offer feline herpesvirus PCR on fresh-frozen biopsy samples.

Cutaneous manifestations of feline herpesvirus can be difficult to resolve, and the prognosis is guarded. Several treatment options are available that can manage, although not always cure, this condition. L-lysine, which inhibits herpesvirus replication by blocking the availability of the amino acid arginine, can be effective at a dosage of 200 to 500 mg/cat orally twice daily. Interferon- α (IFN- α), a cytokine with antiviral properties, has also been used to treat this virus, but the dosages reported in the literature vary wildly. Dosages ranging from 30 units/cat/day orally to 250 to 500 units/cat orally three times weekly and 10,000 units/kg subcutaneously twice daily have been reported, with the 30 units/day-dosage used most commonly for dermatologic conditions. Imiquimod (Aldara), a topical cream for treatment of human genital warts caused by papillomavirus whose exact mechanism is unknown although interaction with toll-like receptors is considered most likely, can be effective in these cats when applied every 48 to 72 hours. Topical and oral glucocorticoids are contraindicated.

FELINE CALICIVIRUS

Feline calicivirus (FCV), a virus in the Caliciviridae family, is a common cause of ocular discharge, nasal discharge, oral ulceration, and conjunctivitis in felines. It has been isolated from some cases of feline chin acne, although it is unknown whether this was an incidental finding. Twenty five percent of animals that are infected with this virus become chronic carriers and relapse with clinical symptoms when faced with stressful symptoms, as with feline herpesvirus.

Recently a severe hemorrhagic virulent form of FCV was reported that produced a mortality rate of 33% to 60% (Pesavento et al., 2004). Systemic signs exhibited by these cats included fever, anorexia, and diffuse edema. An ulcerative, crusting dermatitis of the face, ears, and feet was also a symptom in many symptomatic animals. Histopathology of skin lesions was characterized by necrosis of the epidermis and ballooning degeneration of the epidermis, with immunohistochemistry identifying the presence of FCV antigen.

Many affected cats in the literature were current on their calicivirus vaccine, but it appeared to not be protective against this viral strain. Treatment consisted of supportive care, and at this time no effective treatment has been developed in case of another outbreak.

FELINE LEUKEMIA VIRUS

FeLV is caused by a retrovirus typically transmitted by bite wounds, although it can also be transmitted by close contact with nasal and salivary excretions. It causes generalized immunosuppression.

In the early 1990s it was reported that some FeLV-positive cats can have a distinctive giant cell dermatoses, in which the FeLV antigen can be detected by immunohistochemistry in the epidermis (Gross, 2005). Common clinical signs include alopecia, crust, and an exfoliative dermatitis that typically involves the head and muzzle but can be diffuse. Pruritus has been a clinical feature in the majority of reported cases. Diagnosis is made with histopathology and immunohistochemistry, and no successful treatment has been reported to treat this disease.

Cutaneous horns (i.e., protruding growths of keratin) have been associated with several conditions, including squamous cell carcinoma, viral papillomas, dilated pores, and FeLV. Because the horns associated with all of these conditions appear similar, it is important to perform blood testing for FeLV and immunohistochemistry on feline cutaneous horns to evaluate for the possibility of FeLV or papillomavirus-induced horn formation. When the horns are secondary to FeLV, surgery or laser procedure can be performed to remove them, but these cases are prone to relapse because of the difficulty in controlling the underlying viral infection. Although its efficacy on FeLV-positive cats with dermatologic symptoms has not been specifically evaluated, feline IFN at a dosage of 1 million units/kg/day subcutaneously once daily for five consecutive days in three series at day 0, 14, and 60 improved clinical signs and decreased mortality levels in FeLV and feline immunodeficiency patients (de Mari et al., 2004). These findings were statistically significant, and this treatment should be considered as a way to alleviate dermatologic symptoms.

FELINE IMMUNODEFICIENCY VIRUS

FIV is a naturally occurring lentivirus predominantly transmitted between cats via bite wounds. Early stages of the disease can go unnoticed by the owner, but later stages are characterized by myeloid or lymphoid tumors, neurologic symptoms, and secondary infections caused by immunosuppression. At this time there is no effective treatment or prevention for this disease, although feline IFN can be used as described for FeLV skin disease since it has been shown to decrease clinical signs and improve mortality rates in cats coinfecting with FeLV and FIV.

At this time, no unique dermatoses have been associated with this disease, but cats with FIV are prone to several conditions secondary to the immunosuppression caused by this disease. Bacterial folliculitis, dermatophytosis, demodectic mange, and notoedric mange are the more commonly occurring skin conditions secondary to FIV infection, although atypical mycobacteriosis, subcutaneous abscesses, cowpox infections, and cellulitis all have been reported.

FELINE PAPILLOMAVIRUS

Papillomaviruses are very species-specific viruses that tend to favor the stratified squamous epithelium. Papillomavirus infections have been reported in several wild cats such as the snow leopard, Florida panther, Asian lion, and domestic cat (Sundberg et al., 2000). There are few cases of domestic cats reported in the literature, but based on the small sample population, Persians appear to be overrepresented.

As discussed in the FeLV section, cats with papillomavirus can develop cutaneous horns on their paw pads; for this reason papillomavirus immunohistochemistry should be performed on horns.

Papillomavirus has been associated with flat viral plaques that appear as slightly scaly, irregular raised lesions typically under 8 mm in diameter. Diagnosis is made by detecting papillomavirus in samples with either immunohistochemistry or PCR. These lesions can be subtle to discover, and it has been postulated that they may be the early form of Bowen's disease or cutaneous squamous cell carcinomas in situ in some cats. It has been demonstrated that as many as 48% of cats with Bowen's disease can be positive for papillomavirus antigens (Friberg, 2006). Antiviral therapy has been an effective treatment in many of these cases.

Numerous treatment options are available for felines with papillomavirus-induced skin lesions resulting in cutaneous horns, viral plaques, and Bowen's disease. Depending on the lesion, laser ablation can be an effective treatment. Imiquimod can be used on all of these lesions every 48 to 72 hours, with clinical remission possible in many cases. Other protocols use imiquimod every 24 hours for 2 to 3 consecutive days of each week.

A fibroblastic proliferation triggered by papillomaviruses has been reported in the cat and is termed *fibropapilloma* or *feline sarcoid*. Affected cats typically present with singular or multiple firm nodules on the nose, lip, paws, ears, tail tip, and rarely the oral cavity. They have been mainly reported in domestic cats living in rural areas, especially "barn" cats. These lesions can be difficult to differentiate from spindle cell tumors with histopathology and immunohistochemistry. Although surgery is an option, recurrence at surgical site prompted cryosurgery, radiation therapy, and amputation to be previously recommended as the treatments of choice. However, a recent study found imiquimod cream to show 75% or greater improvement in 80% of equine sarcoid lesions (Nogueira et al., 2006). Although studies need to be conducted evaluating its efficacy on feline sarcoids, imiquimod may be a reasonable therapy to start with before progressing to more aggressive therapies.

FELINE COWPOX

Dermatologic lesions secondary to cowpox, a virus in the *Orthopoxvirus* genus, have been reported in cats in the United Kingdom and continental Europe but not the United States. Cats become infected by hunting and eating rodents, which are the reservoir of this virus. This condition is zoonotic, and animals suspected of having it should be handled accordingly.

Cats with cowpox can have mild upper respiratory symptoms, anorexia, and depression; but most display

a primary dermatologic lesion of an ulcerating macule or plaque and secondary lesions 7 to 10 days later of disseminated macules, papules, and nodules.

Differential diagnoses of this condition include deep fungal infections, atypical mycobacteria, nocardia, and neoplastic conditions. Diagnosis is made by histopathologic presence of large epithelial eosinophilic intracytoplasmic inclusions (type A inclusion bodies), and by isolation of the cowpox virus using PCR or immunohistochemistry on dried crust lesions.

No definitive treatment is available, but L-lysine, IFN- α , and Imiquimod can be attempted as described for feline herpesvirus infections. Extreme care should be used when treating these cats topically because of the highly zoonotic nature of this disease.

CHAPTER 100

Canine Papillomaviruses

MASAHIKO NAGATA, Tokyo, Japan

The papillomavirus (PV) was first described in 1933, when Shope recognized the causative agent responsible for cutaneous papilloma in the cottontail rabbit. Watrach (1969) first recognized the structural characterization of the canine PV (CPV) in 1969. Yet this group of viruses has been refractory to standard virologic study because all efforts to date that have been aimed at tissue culture propagation of any of the PVs have remained unsuccessful. Since the mid-1980s there has been a virtual explosion in research and interest in the PVs because differentiation of PV by cleavage patterns produced by treating viral deoxyribonucleic acid (DNA) has emphasized the heterogeneity of the PVs.

VIRAL PROPERTIES

The PVs are grouped together with the polyomaviruses to form the papovaviruses. The PV is a small, naked virus with double-stranded, circular DNA. The size of the CPV has been estimated at 33 to 49 nm; the particles form closely packed crystalline structures within the nuclei. The lack of a lipid envelope may account for the relative resistance of the virus to physical or chemical destruction. PV infections appear to be limited to the epidermis and epithelium. Epidermal DNA is present in the basal layer of the epidermis, and viral replication depends on epidermal cellular differentiation. The site of viral latency is in the

basal layers, although complete viral particles are found at the granular level. The viral genome is divisible into several major early (E) and late (L) open reading frames. The early viral proteins E1 and E2 play a role in replication of the viral genome; and E5, E6, and E7 control cell growth and cell cycle to maximize viral DNA replication. The function of E3 and E4 is not well known, and E3 is expressed in only BPV1, whereas the late protein L1 and L2 genes encode for viral capsid proteins. More than 90 different strains of PVs have been identified in humans, but only three genetically distinct PV types have been sequenced thus far in dogs.

CLINICAL FEATURES

The clinical manifestation of PV depends on the host, the PV type, and the anatomic site infected, even though the most common outcome of PV infection may be asymptomatic infection. Clinical and histopathologic features, as well as the viral strains identified by transmission studies, immunohistochemistry, in situ hybridization methods, and polymerase chain reaction, have suggested that there are at least five or more distinct PV-associated skin disorders in dogs.

Canine Oral Papilloma

Canine oral papilloma (COP) is a self-limited infectious disease that is normally confined to mucosal tissue of the oral cavity or lips in young dogs, but it also can produce papillomas on the conjunctiva and external nares. The lesions begin as white, flat, smooth, shiny papules and plaques and progress to whitish-gray, pedunculated or cauliflower-like hyperkeratotic masses. Light microscopy revealed papillomatous proliferations of thick squamous epithelium, in which some cells are swollen with vesicular cytoplasm. Canine oral PV (COPV)-induced generalized papillomas occasionally may be the presenting sign in immunosuppressed and cyclosporine-administered dogs (Favrot et al., 2005). The lesions regress spontaneously in most cases, although malignant transformation into carcinomas has been reported.

Cutaneous Exophytic Papilloma

Cutaneous exophytic papilloma (CEP) occurs at any age but is most often seen in dogs less than 2 years of age. CEP lesions may be single or multiple and occur mainly on the head, eyelids, and feet. The lesions present as white, pink, or pigmented papillated masses that may be sessile or pedunculated. Lesions are typically less than 1 cm and have a fimbriated surface. Microscopically CEP consists of marked epithelial proliferations on numerous thin fibrovascular stalks. Many but not all CEPs spontaneously regress over a period of weeks to months.

Cutaneous Inverted Papilloma

Cutaneous inverted papilloma (CIP) was described by Campbell and associates (1988) as single or multiple non-pigmented, small, raised, firm masses covered by skin with a central pore opening to the surface. It is usually seen in dogs less than 3 years of age and occurs commonly on the ventral abdomen and groin. Lesions are less than 2 cm and

are supported by thin fibrovascular stalks. Light microscopy shows an inverted flasklike structure below the level of the normal epidermis. CIP usually does not undergo spontaneous regression, although a spontaneously regressed case has been reported (Shimada et al., 1993).

Canine Pigmented Plaques

PV-associated canine pigmented plaques (CPPLs) have been reported by Nagata and associates (1995) to occur in some pugs and miniature schnauzers during young adulthood. Boston terriers, French bulldogs, and shar-pei, as well as immunosuppressive individuals, are also suspected to have an increased incidence of this wart (Gross et al., 2005; Stokking et al., 2004). Lesions are multiple, scaly, deeply pigmented macules, plaques, and sometime papules commonly seen on the ventral neck, ventral trunk, and extremities. CPPLs develop progressively over time and never regress. The potential for transformation to squamous cell carcinoma (SCC) has also been reported. The presumed familial nature of CPPLs suggests that it is equivalent to epidermodysplasia verruciformis (EV) in humans. EV is considered to be genetically determined and is caused by unusual susceptibility to EV-specific human PV infection.

Canine Pigmented Papules

PV-associated canine pigmented papules (CPPAs) have been reported to occur in a boxer under long-term corticosteroid therapy by Le Net and colleagues in 1997. Multiple black, rounded papules up to 2 mm were recognized on the ventral skin. Histologically the lesions consisted of well-demarcated cup-shaped foci of epidermal endophytic hyperplasia with marked parakeratosis and no papillary proliferations. Spontaneous regression occurred within 3 weeks after cessation of corticosteroids.

Miscellaneous Forms Suggesting Different CPV Infestations

Canine Digital Papillomatosis

Multiple papillomas, strictly limited to the junction of the footpad and adjacent skin and not involving footpads on all four feet, was reported to occur in a 9-month-old intact male beagle (Debey et al., 2001). Histopathologic findings were similar to those of CPPAs, and immunohistochemical and electron microscopic study confirmed the presence of CPV particles. All of the papillomas had been completely resolved within 2 months after diagnosis. These distinctive clinical and histologic findings could be associated with a novel CPV, even though the PV has not been cloned yet.

Nail Bed Inverted Squamous Papillomas

Nail bed inverted squamous papilloma has been described as a single swollen digit, usually with a thickened, abnormally soft nail, which may be broken or absent (Gross et al., 2005). Histopathologic features show a well-circumscribed, cup-shaped, thick layer of squamous epithelial cells that form papillary projections extending into the keratin core. Occasional epithelial cells may exhibit cytoplasmic vacuolation resembling koilocytosis, even though neither papillomaviral DNA nor antigens have been demonstrated.

Canine Genital Papillomatosis

Canine genital papillomatosis is probably caused by a different CPV, since neither the oral nor the cutaneous CPV induces tumors of the lower genital tract. This form of CPV infection is less frequently reported and has yet to be given a properly detailed description.

Squamous Cell Carcinoma

PVs appear to be involved in the etiology of certain forms of SCC in dogs. Sundberg and O'Banion (1989) reported that some dogs treated with a live virus vaccine made from PV isolated from naturally occurring COP experienced SCCs at their vaccine inoculation sites. In naturally occurring SCC, COPV DNA was demonstrated in nests of the epithelial tumor cells surrounding horn pearls or disseminated in the carcinoma tissue (Teifke, Lohr, and Shirasawa, 1997). In addition, PV-associated SCC in situ following chronic administration of cyclosporine and prednisone and invasive SCC related to bone marrow-transplanted canine X-linked severe combined immunodeficiency have also been reported in dogs (Calla, Preziosi, and Mauldin, 2005; Goldschmidt et al., 2006). It was suggested that a progression of viral papillomas into carcinomas in dogs may occur and that a genetic variety of CPV exists.

TREATMENTS

The search for an effective treatment against PV-associated skin diseases has been frustrated by the nature of CPV immunity, which remains inadequately understood at this time. In addition, PVs are very resistant within the environment and are difficult to eliminate with disinfectants. Fortunately routine treatment of these lesions is not crucial. The majority of PV infections regress spontaneously after the development of a cell-mediated immune response, and older animals have developed solid immunity as a result of previous exposure to the virus. However, lack of regression of the papillomas, interference with function, cosmetic embarrassment, or risk of malignancy may indicate vigorous therapy. In humans no treatment has yet had a very high success rate (average 60% to 70% clearance in 3 months), and the highest clearance rates for various treatments are usually found in younger individuals who have a short duration of infection. The use of surgery and destructive therapies such as cryotherapy and laser therapy have been discussed in the previous edition of the text (Bonagura, 2000); antiviral treatments are the focus of this revised chapter and represent the most current therapies for PV-associated skin diseases.

Immunotherapy

Imiquimod (Aldara, 3M Pharmaceuticals), an imidazoquinoline amine, is an immune response modifier (see Chapter 93). Imiquimod differs in that it does not have direct antiviral properties but rather it induces a significant production of cytokines, including interferon (IFN)- α , IFN- γ , interleukin (IL)-6, IL-12, and tumor necrosis factor- α . These cytokines stimulate the helper T cell (Th) Th1 pathway and inhibit the Th2 pathway via stimulation of monocytes and dendritic cells. In addition, imiquimod activates immune cells

via binding to cell surface receptors such as the toll-like receptors that play an important role in host defense by regulating both innate and adaptive immune responses. Moreover, imiquimod was found to be effective in human cutaneous premalignancies and malignancies. Since tumor development depends on blood vessel supply, the inhibition of angiogenesis could be responsible for the antitumor activity. In humans imiquimod is applied before bedtime and after washing areas to be treated once a day for 3 days a week. It is well tolerated; but occasional side effects include erosion, excoriation, flaking, edema, and erythema. No controlled studies have been reported in dogs, and the cost is fairly high.

Autogenous vaccines have been used especially for treatment of mucous membrane warts in humans and dogs. It has been demonstrated by Bell and associates (1994) that systemic administration of a formalin-inactivated COP vaccine can protect against mucosal infection with COPV. In this study 26 dogs received two doses of phosphate-buffered saline intradermally, and 99 dogs received two doses of the inactivated vaccine. One month after the second dose, all dogs were challenged with infectious COPV by scarification of the oral mucosa. All control dogs acquired papillomas 6 to 8 weeks after infection, whereas none of the vaccinated dogs did. Sundburg and associates (1994) reported that the vaccine might be protective against COPV epidermal infections that develop as a consequence of the spread of oral lesions to the skin in immunosuppressed dogs. In addition, the vaccination might play a role in protecting against the development of SCC in dogs infected with COPV.

Sensitization to dinitrochlorobenzene followed by an application of dinitrochlorobenzene to lesions and contact sensitization with diphenylcyclopropenone has proven to be a useful treatment of cutaneous malignancies and refractory warts in humans. However, such treatment has been tried in only a limited number of human studies, and no canine studies have been conducted.

Antiviral Therapy

IFN is produced in the body and exerts the biologic action to protect cells from any kind of virus infection. There are three main classes of human IFNs (i.e., IFN- α , IFN- β and IFN- γ , as well as a minor class called IFN- ω). IFN- α elicits broad activities inhibitory to virus replication (also see Chapter 85). An intracellular mechanism, by which IFN- α 2a inhibits human papillomavirus (HPV)-transformed cell proliferation and presumably HPV-induced papillomas, operates through the suppression of viral oncoprotein expression and the cytostatic arrest of cycling at G1. In dogs it was reported that 1.5 to 2 million units/m² of IFN- α 2a (Roferon-A, Hoffman-LaRoche) given subcutaneously three times a week is effective for the treatment of severe cases of oral or cutaneous viral papillomatosis or both. In addition, IFN- α 2a therapy, 1000 units given orally on a 21-day on, 7-day off schedule was reported as an adjunctive therapy for CPPLs (Stokking et al., 2004). The effectiveness of IFN- α 2b (Intron A, Schering-Plough), 30 units/ml given orally, has been reported anecdotally, but the recommended dose and frequency varied widely. In some instances combining IFN- α with other treatments could increase the likelihood of effective treatment.

Besides IFN- α the efficacy of IFN- γ therapy has been evaluated in several studies in humans, but it remains controversial. There are no reports on use of IFN- γ in dogs, although one report (Andre, 2004) indicated that IFN- ω could be useful as an alternative with the aim of reducing the size of papillomas. A 4½-month-old dog with papillomatosis on the mucocutaneous junctions was treated with 2 million units (MU) of intralesional IFN- ω (Virbagen Omega, Virbac; Intercat, Toray). The lesions regressed in both size and number without side effects and were removed surgically. Furthermore, my experience has suggested that IFN- ω , 1 MU/kg given subcutaneously three times a week for a month, could be helpful in the treatment of CPPL.

In humans the common side effects of IFN treatment are the influenza-like symptoms such as fever, chills, nausea, fatigue, myalgia, and loss of appetite. Such side effects usually show a tendency to be less severe with time and are usually tolerable. It should be emphasized that no properly controlled studies nor any safety studies on IFN therapy against canine papillomatosis have been conducted so far; thus IFN is best considered as a treatment of last resort because of its high cost and inconsistent effects.

CHAPTER 101

Pyotraumatic Dermatitis ("Hot Spots")

WAYNE S. ROSENKRANTZ, *Tustin, California*

Hot spots, more appropriately described as pyotraumatic dermatitis, are defined as a circumscribed, moist exudative area that is most commonly brought on by self-trauma. The self-trauma results from attempts to alleviate pain or pruritus associated with an underlying disease that is creating this sensation. Primary bacterial infections are very rare and in theory could create localized moist exudative lesions with minimal self-trauma.

The most common causes of hot spots are allergic conditions such as flea allergy, atopic dermatitis, adverse food reaction, scabies, and anal gland problems (Box 101-1). Clipping or grooming complications such as razor burn or trauma can also create localized inflammation that results in pruritus and hot spot formation. Occasionally other infectious conditions (*Staphylococcus* spp., *Pseudomonas* spp., demodicosis, or dermatophytosis) can result in localized multifocal

Box 101-1

Causes of Hot Spots**Common Causes**

Allergies: flea, atopy, food
 Parasitic: scabies, *Demodex*
 Anal gland disease
 Clipping or grooming
 Result of deep pyoderma

Uncommon Causes

Dermatophytosis
 Injection site reactions
 Drug reactions
 Autoimmune disease
 Panniculitis
 Vasculitis

areas of pain and pruritus leading to hot spot-like lesions. Other less common causes of hot spots are listed in Box 101-1.

Although any breed of dog can experience hot spots, some consider certain breeds to be predisposed. These include the golden retriever, Labrador retriever, St. Bernard, collie, and German shepherd. However, many of these breeds are actually predisposed to the common underlying causes of hot spots such as allergies. Long-haired coat length has also been thought to be involved with a predisposition to hot spots. However, in a report on 40 dogs 50% had short hair, and 50% had long hair (Schroeder et al., 1996).

The role of *Staphylococcus* in the development of hot spots remains controversial. *Staphylococcus* can be isolated from the skin of normal dogs. Higher numbers of these organisms are found in allergic dogs, even in those without active skin disease. Therefore allergies may contribute to hot spots not only by the presence of pruritus but also by creating a favorable environment for larger numbers of staphylococci to flourish on the skin. One investigator proposes that hot spots are of two types based on histopathologic patterns (Reinke et al., 1987). One is a superficial lesion in which bacteria are considered surface colonizers. The other is a folliculitis that may be a deep lesion. Coagulase-positive *Staphylococcus* spp., particularly *Staphylococcus intermedius*, are most commonly cultured from these lesions. This same study showed a strong tendency for young dogs, golden retrievers, and St. Bernards to be predisposed to the deeper form of hot spots. In a more recent evaluation, 44 privately owned dogs in a flea scarce environment had their lesions separated histopathologically into four patterns by the presence or absence of eosinophils and/or folliculitis (Holm et al. 2004). Eosinophils have not previously been recorded in pyotraumatic dermatitis but were seen in 29 cases. Acute folliculitis was seen in 20 cases. However, no correlation was seen among age, sex, breed, underlying cause, or site of lesion and histopathology. Twenty-seven cases were cultured for bacteria, of which 25 grew *S. intermedius* and two were negative. In another study *Staphylococcus* was isolated from all lesions before topical treatment (Schroeder et al., 1996). The condition in placebo vehicle control groups cleared completely within 7 days without topical antimicrobial treatment. The role of *Staphylococcus* as a primary cause in hot spots is certainly unclear.

CLINICAL FEATURES

The historical hallmark of hot spots is intense pruritus, and it represents one of the situations in which clients are generally correct when reporting that the lesion “just happened.” The intense self-trauma can produce large lesions in minutes.

Regardless of the cause, most hot spots look similar clinically. They are generally well circumscribed, moist, erosive-to-ulcerated, erythematous, and usually painful lesions. The overlying hair is matted and coated with a serous-to-suppurative exudative discharge. Variable amounts of crusted debris may be present. It is not uncommon to see peripheral smaller lesions adjacent to the primary site. Acute lesions tend to be edematous, whereas chronic lesions may be thickened with lichenified-to-scarred peripheral areas resembling acral lick dermatitis. The most common body locations for pyotraumatic dermatitis include the rump, lateral upper thigh, perineal-rectal area, and lateral aspect of the face below the ear. The rump and lateral upper thigh are the most common locations and can be associated with flea allergy, adverse food reactions, or atopic dermatitis. The perineal-rectal area lesions generally are caused by anal gland disease or adverse food reactions (see Chapter 87). The lateral cervical facial lesions can be caused by ear problems, atopic dermatitis, or adverse food reactions.

DIAGNOSIS

Diagnosis is generally made from the history and physical examination. The intensity of pruritus, body location, and physical appearance are often all that is necessary to make a diagnosis. Initially skin scrapings and cytologic studies should be considered to rule out *Demodex* infection and determine if cocci are present. In more chronic or relapsing conditions, fungal and bacterial cultures, biopsies, and allergy workups (allergy testing and elimination diets) should be performed. If these tests do not lead to a diagnosis, laboratory testing for underlying immune-mediated or systemic problems should be performed.

THERAPY**Topical Therapy**

Regardless of the cause and independent of what is used either topically or systemically, shaving the hair and cleansing the hot spot is the initial form of therapy. To shave or clean the wound, a topical desensitizing agent or sedation may be necessary because of the pain and discomfort associated with the lesion. After the area is clipped, the full extent and nature of the lesion can be observed. An antimicrobial shampoo containing benzoyl peroxide (Oxydex, Sulf/Oxydex, Eliminate Ivax/DVM Pharmaceuticals; Pyoben, Virbac; Micro Pearls benzoyl peroxide, Vétoquinol; DermaBenSs, DermaPet) or chlorhexidine (ChlorhexiDerm, Eliminate Ivax/DVM Pharmaceuticals; Hexadene, Virbac; Nolvasan; and Douxo, Sogeval) are my favorites. Over-the-counter antimicrobial shampoos such as those containing benzalkonium chloride can also be effective.

After the site is clipped and washed appropriately, additional topical and, in some situations, systemic treatments are needed. Occlusive vehicles (ointments and creams) should be avoided. Nonocclusive vehicles (sprays, rinses, gels, and lotions) are preferable to allow exudation to occur and prevent occlusion of follicles and progression into a deeper folliculitis.

Many practitioners like to use an astringent for the first 24 to 48 hours on hot spots. Astringents precipitate proteins and usually do not penetrate deeply. These products do tend to dry out and decrease the exudation. An example of a currently used astringent is aluminum acetate solution (Burow's solution, Domeboro, Bayer) diluted 1:40 in cool water. Other less commonly used astringents include 5% tannic acid, 25% silver nitrate solution, and potassium permanganate 1:1000 to 1:30,000 solution. I prefer Domeboro because it is tolerated best and does not stain compared with the other astringents.

The most common topical products used on hot spots are antipruritic sprays, gels, and lotions. Some of these products substitute another sensation for the pruritus such as heat or cold. Cooling tends to decrease pruritus. Examples include 0.12 to 1% methol, 0.12 to 1% camphor, 0.5 to 1% thymol, or cold ice packs. Other products use local anesthetic or desensitizing agents such as benzocaine, tetracaine, lidocaine, 1% pramoxine (Relief, Eliminate Ivax/DVM Pharmaceuticals; Dermacool, Virbac), benzoyl peroxide (Oxydex Gel, Eliminate Ivax/DVM Pharmaceuticals; Pyoben Gel, Virbac), and tars. These agents are short acting. Topical antihistamines are considered effective in humans but in my experience have limited value in the dog. Anecdotal reports suggest that topical 2% diphenhydramine (Histacalm, Virbac) is effective in reducing pruritus in dogs with hot spots. Colloidal oatmeal rinses and shampoos can also give topical relief from pruritus. Commonly used products include Epi-Soothe (Virbac) and Aveeno (Rydelle). The most effective topical products in controlling the pruritus associated with hot spots are glucocorticoids. Hydrocortisone is the safest and is anecdotally effective. Hydrocortisone 1% is considered particularly safe and can be used long term with no adverse topical or systemic side effects. The most commonly used veterinary products include CortiSpray (Eliminate Ivax/DVM Pharmaceuticals), Dermacool-HC (Virbac), Cortisoothe (Virbac), and CortiCalm (Eliminate Ivax/DVM Pharmaceuticals). A newer low-dose 0.015% triamcinolone spray (Genesis, Virbac) also has been evaluated and appears to be much more effective than the hydrocortisone-based products; in controlled studies it appeared to have no significant systemic absorption. However, when applied to the flanks and medial thighs, localized cutaneous atrophy reactions have been seen.

Topical antimicrobial agents can be used alone or in combination with other ingredients. Alcohol-based products can be bactericidal and astringent but also can be irritating to ulcerated surfaces. The most commonly used alcohol product is 2% benzyl alcohol. Some of the active agents mentioned in the shampoo section are also available in gel and solution forms and can be used on focal lesions. Chlorhexidine diacetate or gluconate and 2.5 to 5% benzoyl peroxide gels (Oxydex, Eliminate Ivax/DVM Pharmaceuticals; Pyoben, Virbac) are examples. One of the

oldest antimicrobials is iodine. The "tamed" iodines (povidone-iodine [Betadine] and polyhydroxydine [Xenodine]) are less irritating and less staining than their precursors but generally are not as effective as some of the other antimicrobials mentioned. Surface-acting agents such as the quaternary ammonium compounds (e.g., benzalkonium chloride) are effective broad-spectrum antibacterial agents.

Many potent topical antibacterial agents are available. My favorite veterinary topical antibiotic is mupirocin because of its high efficacy for coagulase-positive staphylococci and its ability to penetrate deeper pyodermas. Veterinary products are no longer available but can be formulated by compounding pharmacies. Other products that can be helpful include neomycin, gentamicin, bacitracin, and polymyxin B.

Combination antibiotic and glucocorticoid products often produce the best results and quickest healing. One study (Schroeder et al, 1996) supported this when neomycin, prednisolone, and neomycin-prednisolone products were compared. The combination product produced the quickest recovery. The most commonly used veterinary products include Tresaderm (Merial), Gentocin topical spray (Schering-Plough) and generics, Panolog (Fort Dodge), and Otomax and Mometamax (Schering-Plough). Because these products contain potent glucocorticoids, their use should be limited and are not for the long term.

Systemic Therapy

The need for systemic therapy for hot spots varies on a case-by-case basis. Most dogs benefit from a course of systemic antibiotics, particularly if the hot spot represents a deeper folliculitis. Antibiotic selection should be based on proven efficacy for *S. intermedius* and should be used for a minimum of 14 days and generally continued 7 to 10 days beyond clinical cure. My personal favorites include cephalexin, 20 to 30 mg/kg every 12 hours; ormetoprim-sulfadimethoxine (Primor, Pfizer Animal Health), 55 mg/kg for the first 24 hours and then 27.5 mg/kg every 24 hours after that; amoxicillin-clavulanate (Clavamox, Pfizer Animal Health), 15 to 20 mg/kg every 12 hours; and enrofloxacin (Baytril, Bayer), 5 mg/kg every 24 hours, or marbofloxacin (Zeniquin, Pfizer Animal Health), 2.5 mg/kg every 24 hours.

The use of systemic glucocorticoid therapy is more controversial. Some dermatologists avoid glucocorticoids, especially for deeper pyotraumatic folliculitis, arguing the concern for immune depression. Certainly if the practitioner elects to use glucocorticoids, long-acting injectables should be avoided, and only short courses of oral prednisone or prednisolone should be used to break the pruritic cycle. Suggested dosages would include antiinflammatory dosages (1 mg/kg every 24 hours for 3 to 5 days).

The client should be warned about future lesions because this is commonly a recurring problem if the underlying disease is chronic. Therefore identifying, eliminating, or controlling the underlying disease is the long-term goal for prevention of hot spots. The client should be educated about the various differentials, and diagnostic tests should be performed accordingly. Attention to increased episodes of pruritus after grooming and bathing should be stressed.

Maintaining parasite control and routinely examining the ears and anal glands are also recommended.

CHAPTER 102

Methicillin-Resistant Canine Pyoderma

CARLO VITALE, San Francisco, California

The emergence of methicillin-resistant *Staphylococcus aureus* in humans in 1961 in the United Kingdom set the stage for the need of a more globally organized monitoring and surveillance program. This allowed the medical world to institute preventive programs, outline responsible antibiotic usage, and encourage research to adapt accordingly to the inevitable increase in resistance. In veterinary medicine there are very basic recommendations and guidelines for the judicious use of antibiotics. Unfortunately there is no specific guidance or systematic surveillance programs for veterinarians regarding the proper use of antibiotics.

Methicillin is a penicillin-type antibiotic that is no longer available in any form; thus oxacillin is used as a marker for methicillin resistance. On the basis of bacterial culture and susceptibility testing, resistance to oxacillin also proves resistance to all penicillins and cephalosporins (beta-lactams). Acquisition of an altered penicillin-binding protein 2a (PBP2a) renders species of *Staphylococcus* resistant to methicillin. This resistance occurs when a bacterial isolate carries and mobilizes PBP2a, encoded by the gene *mecA*. The terms *methicillin-resistant S. aureus* (MRSA) and *Staphylococcus intermedius* (MRSI), are preferred over the term oxacillin-resistant *Staphylococcus*.

INCIDENCE

Historically, *S. intermedius* is the most common bacterial isolate from cases of canine pyoderma. It appears, however, that many strains previously identified as *S. intermedius* are *S. pseudintermedius*, as shown recently through multilocus sequence typing (Bannoehr et al., 2007). According to most commercial veterinary reference lab-

oratories, methicillin-resistant strains of *Staphylococcus intermedius* are not uncommon. The clinical presentation of methicillin-resistant pyoderma generally does not differ from routine cases. Articles have been published documenting methicillin resistance in cases of *S. intermedius* (Cole et al., 2004; Gortel et al., 1999; Morris et al., 2006). Interestingly, in another study 2 of 57 *S. intermedius* isolates were resistant to methicillin; however, about half of the total expressed PBP2a, indicating that the genetic capability is present to be resistant under the right conditions (Kania et al., 2004).

Since most of the attention has been given to methicillin-resistant *S. aureus* in animals, it is clear that there has been a definite increase in the numbers of reports of MRSA infections in pets (Baptiste et al., 2005; Gortel et al., 1999; Kania et al., 2004; Loeffler et al., 2005; Morris et al., 2006). *Staphylococcus schleiferi* has recently been associated with cases of canine pyoderma and has demonstrated methicillin resistance (May et al., 2005; Morris et al., 2006). MRSA and methicillin-resistant *S. schleiferi* appear to be rare in dogs. Most strains of methicillin-resistant *Staphylococcus* are not multidrug resistant. However, the true incidence of methicillin-resistant *Staphylococcus* in dogs is not known because of the paucity of large-scale studies.

ZOONOSIS

MRSA is considered to be an emerging reverse zoonosis (human-to-animal transmission). There have been several documented cases of likely transmission of MRSA from humans to animals (Weese et al., 2006; O'Mahony et al., 2005; Tomlin et al., 1999; Manian 2003, van Duikeren

et al., 2004). Transmission of MRSA to pets via contact with infected humans likely results in colonization (primarily nasal and rectal), infection, or both. In addition, some of these reports have shown that pets can serve as a “reservoir,” thus allowing transmission back to the owner. I have seen several cases of nasal colonization with MRSA in dogs that acted as a source for reinfection to individuals who had intimate contact with the affected pet. In these cases the exact same strain was isolated from the dog's and the owner's nares, and only after nasal clearance of the dog did the owner's lesions cease to recur. Apparently it is believed MRSA colonization in pets usually is a transient occurrence.

MANAGEMENT AND THERAPY

Overall practicing veterinarians have received little in the way of specific detailed guidelines regarding the proper use of antibiotics for the treatment of methicillin-resistant canine pyoderma. The following recommendations may be useful to establish treatment success and possibly reduce the risk of further antibiotic resistance.

The most common first-line antibiotic prescribed empirically for routine canine pyoderma is cephalexin. The American College of Veterinary Internal Medicine and several university teaching hospitals have guidelines for the general use of antibiotics. Some of these institutions have found it useful to separate antibiotic usage into three different categories: first-line, second-line, and third-line (Weese, 2006b). In all cases of chronic and/or recurrent canine pyoderma, bacterial culture and susceptibility testing is recommended, and treatment is based on the results. However, some veterinary reference laboratories may provide inadequate or poor results with regard to culture and identification or susceptibility testing. When submitting bacterial culture and susceptibility testing, I suggest that veterinarians alert the laboratory that they are concerned about methicillin resistance, which could be supported clinically by a lack of response to cephalexin. In this situation the laboratory may subculture and repeat culture technique to reconfirm oxacillin resistance. Some laboratories are already offering this, but not all laboratories do; contacting your laboratory on their isolation techniques is a good idea. The National Committee for Clinical Laboratory Standards (NCCLS) for humans has new recommendations; we hope our veterinary reference laboratories would follow their advice when applicable. In addition, accurate identification of methicillin resistance can be difficult in some cases because of the presence of different clones (resistant and susceptible) coexisting within the same “pure” culture. This phenomenon is termed *heteroresistance* and occurs mostly with strains of methicillin-resistant *Staphylococci*. Consultation with a microbiologist may prove useful to properly interpret results of susceptibility tests. I have found chloramphenicol or clindamycin to be a superior alternative to cephalexin in cases of documented methicillin resistance. Treatment generally is recommended for

at least 3 weeks in cases of superficial pyoderma and up to 6 weeks in cases of deep pyoderma.

As in all cases of infectious disease, it is extraordinarily important to wash hands thoroughly and frequently after examining each patient. Proper hand hygiene (frequent warm water with soap or waterless alcohol-based rubs) is the single most important factor in preventing infections. Gloves are generally not recommended because most caretakers touch multiple sites and do not change them often enough between patients. In cases of MRSA, all patients suspected or proven to be infected should be managed in a proper isolation ward.

Sebaceous Adenitis

EDMUND J. ROSSER, JR., *East Lansing, Michigan*

Sebaceous adenitis is an inflammatory disease process directed against the sebaceous glands of the skin and has an unknown etiology and pathogenesis (Rosser et al., 1987; Scott, 1986). In standard poodles the results of pedigree analyses and prospective breeding studies of affected animals suggest that sebaceous adenitis is a heritable, autosomal-recessive skin disease of variable expression (Dunstan and Hargis, 1995), and a similar mode of inheritance has been proposed for Akitas with sebaceous adenitis (Reichler et al., 2001).

CLINICAL FEATURES

Sebaceous adenitis occurs primarily in young adult to middle-aged dogs with no apparent sex predisposition. However, more recent reports have indicated the onset of this disease in older dogs, including those in the range of 7 to 11 years of age, and this has also been my experience with this disease (Linek et al., 2005; Reichler et al., 2001). Sebaceous adenitis can be divided into two major forms based on their differences in clinical presentation and histopathologic changes (Rosser, 1992).

The first form occurs in long-coated breeds and has been recognized most frequently in the standard poodle, Akita, and Samoyed. This form of the disease is characterized by a dull, brittle hair coat; alopecia; moderate-to-severe scaling; and the formation of follicular casts. Pruritus and malodor are variable; they tend to be mild or absent early in the course of the disease and may become moderate to severe in advanced cases or when a secondary bacterial folliculitis develops. In standard poodles the lesions most commonly affect the dorsal regions of the body, including the dorsal planum of the nose, top of the head, pinnae, dorsal trunk, and tail. When the disease is progressive, the affected areas develop tightly adherent scales (varying from silver-white to brown, depending on hair coat color) with small tufts of hair matted within the scales. The disease in standard poodles may present in several clinical forms: (1) a subclinical form (detectable only on histopathologic examination of skin biopsy specimens of apparently normal skin); (2) a localized, mild, and self-limiting form; (3) a progressive moderate-to-severe form; and (4) a cyclic form with periods of spontaneous improvement or worsening independent of any treatment. In Samoyeds the alopecia, scaling, and follicular casts most commonly affect the entire trunk and pinnae. The disease in the Akita may represent its own variant of sebaceous adenitis in long-coated breeds of dogs because it differs by the additional presence of greasiness of the skin and hair coat and the frequent presence of papules and pustules. Akitas may also show signs of systemic illness such as fever, malaise, and weight loss (Power and Ihrke, 1990).

However, a more recent study of 23 Akitas reported a progression of the disease similar to that observed in standard poodles, both clinically and histologically, and an absence of any systemic signs (Reichler et al., 2001). It was also reported that 16 of 23 owners of affected dogs in this study reported that an illness, glucocorticoid or progestagen treatment, general anesthesia, estrus, molting, neutering, or an environmental change preceded the onset of the disease.

The second form of sebaceous adenitis occurs in breeds of dogs with short coats and has been most frequently recognized in the vizsla. This form of the disease is characterized by "moth-eaten," annular, or diffuse areas of alopecia and mild scaling with occasional small firm nodules, affecting the trunk, head, and ears. Dogs usually do not have pruritus, and the development of secondary bacterial folliculitis is rare.

DIAGNOSIS

The breed affected, the historical development of the problem, and the physical findings first lead the clinician to suspect sebaceous adenitis. The diagnosis is confirmed by the histopathologic examination of several skin biopsy specimens that are representative of the different degrees of lesion severity noted during the physical examination. Sites selected for biopsy should include any apparently normal skin, mildly affected areas, and severely affected areas. The most common histologic finding is a nodular granulomatous-to-pyogranulomatous inflammatory reaction at the level of the sebaceous glands (Dunstan and Hargis, 1995; Gross et al, 2005).

In the chronic stages of the disease in long-coated breeds of dogs, there is often a complete absence of sebaceous glands with little or no inflammation, perifollicular fibrosis, and marked follicular and surface hyperkeratosis. This may easily be misinterpreted as being consistent with an underlying endocrine skin disease. For this reason it is suggested that such biopsy samples be submitted to individuals specifically trained in veterinary dermatohistopathology. In contrast, in short-coated breeds of dogs, the periadnexal nodular granulomatous to pyogranulomatous inflammatory reaction is usually present throughout the disease process, with occasional complete obliteration and loss of all adnexal structures.

TREATMENT AND MANAGEMENT

Long-term management of sebaceous adenitis can be a frustrating experience for owners and veterinarians because the response to therapy varies, depending on the severity of the disease at the time of diagnosis; in addition, there is a lack of a consistent response to any single treatment regimen. This problem has led to several treatment recommendations and

much confusion about which treatments should be tried. For this reason, I recommend a systematic approach to the treatment of sebaceous adenitis in dogs.

The goal of therapy should be to remove the excess scales, improve the luster of the hair coat, and regrow hair whenever possible (in standard poodles the hair regrowth is usually straight rather than curled). When response to treatment is evident, some level of maintenance therapy is usually required to control the disease. In severe or chronic cases in which the sebaceous glands have been completely lost, the prognosis for accomplishing these goals is guarded. However, a successful response to treatment (White et al., 1995), as well as the reappearance of sebaceous glands (Dunstan, personal communication, 1997), can occur even when the initial histopathologic examination of skin biopsy specimens revealed follicular fibrosis and apparent loss of the sebaceous glands.

Specifically, a significant regeneration of sebaceous glands was observed in dogs with sebaceous adenitis while being treated with cyclosporine for 12 months (Linek et al., 2005). In this study, followup biopsies taken every 4 months over a 12-month time period indicated an increase from only 2% of hair follicles exhibiting sebaceous glands to 40% of hair follicles exhibiting sebaceous glands. However, the severity of the follicular keratosis did not change significantly.

In mildly affected dogs the regular use of antiseborrheic shampoos, conditioners, and emollients and essential fatty acid dietary supplements (Bonagura, 2000, p. 538) may be effective. If the response is inadequate, my first recommendation is the consistent use of a combination of essential fatty acid dietary supplements (Derm Caps ES, DVM Pharmaceuticals, Inc.), one capsule orally every 12 hours; and evening primrose oil, 500mg orally every 12 hours per dog (Rosser, 1992). This treatment should be continued for 2 months before being considered ineffective. Occasionally observed side effects include vomiting, diarrhea, and flatulence. This treatment has been most effective in the standard poodle and Samoyed breeds and usually requires lifelong administration to control the disease. An alternative to this treatment is the use of vitamin A at an initial dosage of 8,000 to 10,000 units BID; if significant improvement is not observed within 3 months, the dosage may be increased to 20,000 to 30,000 units BID (DeManuelle and Rothstein, 2002; Sousa, 2006). When this is ineffective or in dogs with large areas of tightly adherent scales (as in standard poodles), a bath oil treatment can be recommended. This is carried out by mixing any light mineral oil-containing bath oil (e.g., Alpha Keri Bath Oil, Bristol-Myers Squibb Pharmaceuticals or generic bath oil) 50:50 with water and spraying over the entire coat (Blair, 1993). The bath oil is rubbed well into the hair coat and allowed to soak into the coat for 1 hour. The dog should be put in a crate or kennel during the 1-hour soak. The bath oil is then removed by several baths (usually three shampoos) with a liquid dishwashing detergent (e.g., Palmolive dish soap, Ivory dish soap) while the hair coat is scrubbed with a soft hair brush. A conditioner, humectant, or creme rinse (HyLyt, DVM Pharmaceuticals; Humilac, Virbac; Hydra-Pearls, Vetoquinol Pharmaceuticals) should be applied after the final bath. This process results in the removal of a significant amount of the excess scaling, and this treatment alone may control the scaling and allow the regrowth of hair. This procedure

is repeated every 7 days for the first month and then every 14 to 30 days as needed. It must be mentioned that this procedure is relatively labor intensive but can be effective. An alternative to this form of treatment is the use of a 50:50 or 75:25 mixture of propylene glycol and water applied once daily as a spray to the affected areas (Griffin, 1988).

When these treatments have been ineffective, the use of a synthetic retinoid may be considered (see Section V on Evolve). In the management of sebaceous adenitis in vizslas, isotretinoin (Accutane, Roche) has been shown to be a most effective retinoid (Stewart, White, and Carpenter, 1991; White et al, 1995). The recommended dosage of isotretinoin is 1 mg/kg orally every 12 to 24 hours, with improvement usually noticed within 6 weeks. If improvement is evident, an attempt can be made to decrease the dosage to 1 mg/kg orally every 24 to 48 hours for another 6 weeks. If improvement continues, the long-term goal is to control the disease with either 1 mg/kg orally every 48 hours or 0.5 mg/kg every 24 hours.

However, it is important to note that as of this writing, systemic retinoids have become unavailable for use by veterinarians in the treatment of diseases for animals. This is due to recent strict regulations regarding the release of the drug to only registered physicians, and the required use of a human patient consent form when prescribing systemic retinoids.

For management of refractory cases of sebaceous adenitis in long-coated breeds of dogs (primarily standard poodles and Akitas), either isotretinoin or acitretin (Soriatane, Connetics Corp.) can be recommended (Power and Ihrke, 2002). One study indicated that it could not be predicted whether isotretinoin or etretinate would be more effective in the treatment of sebaceous adenitis in any long-coated dog breeds (White et al., 1995). Therefore these dogs can be treated initially with either isotretinoin (1 mg/kg orally [PO] q12 to 24h) or etretinate (1 mg/kg PO q12 to 24h) for an observation period of 6 weeks. Since etretinate is no longer commercially available, acitretin is being considered as the alternative and similarly acting retinoid. If there is a poor response to therapy on the first chosen retinoid, the dog should be switched to the second retinoid for an observation period of 6 weeks. If improvement is noted using either of these retinoids, an attempt can be made to decrease the dosage to 1 mg/kg orally every 24 to 48 hours for another 6 weeks. If improvement continues, the long-term goal is to control the disease using retinoid either at a dosage of 1 mg/kg every 48 hours or 0.5 mg/kg orally every 24 hours.

A treatment option in the management of sebaceous adenitis that has been nonresponsive to retinoid therapy is the use of cyclosporine (Atopica, Novartis) at a dosage of 5 mg/kg orally every 12 hours (Carothers, Kwochka, and Rojko, 1991; Linek et al, 2005; see Chapter 84 for a discussion of the side effects and toxicities in the use of cyclosporine in dogs). Most recently cyclosporine has been applied as a topical solution, using a micro-emulsified cyclosporine oral solution (Neoral, Novartis; 100mg/ml concentration) and mixing 25 ml of the oral solution with 250 ml of water (1:10 dilution), which is then sprayed over the alopecic areas once daily (Patterson, 2005). A response to treatment with evidence of hair regrowth usually occurs within 2 weeks if this regimen is to be effective. If hair regrowth is observed, the treatment may be decreased

from a once-daily application to twice-weekly therapy as maintenance in some cases. In long-coated breeds of dogs the hair should be kept clipped short to facilitate the application of the spray down to the skin. The owners should be instructed to wear gloves during the application process; let the dogs dry for 10 minutes after each application before handling the dog; and apply the spray in the late evening to minimize the handling of the dogs. To date no adverse reactions or toxicities to this treatment have been reported. A conditioner or humectant in a spray form (HyLyt, DVM Pharmaceuticals; Humilac, Virbac; Hydra-Pearls, Vetoquinol Pharmaceuticals) should be used following each treatment with the topical cyclosporine.

Sebacous adenitis appears to be relatively refractory to either antiinflammatory or immunosuppressive dosages of corticosteroids. When a secondary bacterial folliculitis is present, the treatment should include the use of an appropriate systemic antibiotic along with a keratolytic, antibacterial, and follicular flushing shampoo (Sulf Oxydex, DVM Pharmaceuticals, Inc.).

CHAPTER 104

Therapy of *Malassezia* Infections and *Malassezia* Hypersensitivity

DANIEL O. MORRIS, Philadelphia, Pennsylvania

Malassezia dermatitis (MD) and *Malassezia* otitis (MO) are superficial fungal (yeast) infections occurring on and within the stratum corneum of the epidermis of many mammalian species. Canine *Malassezia* hypersensitivity (MH) is a type-1 (immediate) hypersensitivity reaction to soluble allergens produced by the yeast; these allergens are recognized by the host's immune system in a manner similar to aeroallergens and contribute to the pathology of atopic dermatitis (AD). In dogs and cats *Malassezia pachydermatis* colonizes the skin during the immediate perinatal period and is the primary yeast species associated with skin and ear canal disease.

PATHOGENESIS

Malassezia yeast colonizes the skin and external ear canals of animals in very low numbers. Overt "infection," sometimes referred to as "overgrowth," is defined by increased numbers of the yeast on the skin surface in conjunction with inflammation. In a diseased state alterations of the microclimate of the surface of the skin contribute to increased susceptibility to yeast infection. Primary diseases that cause increased moisture, altered surface lipids, and/or disruption of stratum corneum barrier function encourage secondary overgrowth of the organism. Pruritic inflammatory diseases

(allergic and parasitic) result in microclimate changes caused by scratching (disruption of barrier function), licking (added moisture), and increased production of sebum. Endocrinopathies, especially hyperadrenocorticism, directly cause alterations in sebum characteristics and stratum corneum function. Metabolic diseases that result in hyperkeratosis (such as zinc-reponsive dermatosis, hepatocutaneous syndrome/superficial necrolytic dermatitis of dogs, and thymoma-associated dermatosis of cats) also appear to be risk factors. Secondary MD is also associated with primary (idiopathic) seborrhea of dogs and cats and paraneoplastic alopecia secondary to internal carcinomas in cats.

In some dogs with AD, antigens produced by *M. pachydermatis* may be recognized by the immune system as allergens (i.e., MH), in which case a highly inflammatory and pruritic response can be mounted to relatively low numbers of yeast organisms, blurring the line between cytologic definitions of “colonization” and “infection.” However, many dogs with MH also have overt infection, as defined cytologically by overgrowth of yeast on the skin surface (see section on Cytology later in the chapter for guidelines). MH has not yet been studied or defined in cats with allergic skin disease, although MD does appear to contribute to the pruritic threshold of some cats with AD.

CLINICAL SIGNS

Several excellent reviews regarding the clinical presentations of MD and MO in dogs and cats are available (Matousek and Campbell, 2002; Moriss, 1999; Muse, 2000). Some key points are included here.

Although MD is usually intensely pruritic, the only primary lesion produced is erythema. Secondary lesions, including excoriations, seborrheic plaques, lichenification, maceration, and intertrigo, are common and cannot reliably be distinguished from staphylococcal pyoderma without cytologic examination. Therefore look for the yeast on the surface of any pruritic skin lesion.

The clinical appearance of the skin in cases of MD is highly variable. It may either be dry and flaky (seborrhea sicca) or tacky/greasy (seborrhea oleosa). In rare cases *M. pachydermatis* can cause a folliculitis that mimics staphylococcal folliculitis, dermatophytosis, and demodicosis.

The distribution pattern of canine MD is variable but most commonly affects some combination of the face (especially periocular and perioral skin), feet (interdigital spaces and claw folds), intertriginous areas (axillae, groin/inguinal area, facial folds, vulvar and mammary folds), and perineum. Generalized cases of MD may occur in chronic cases of allergic dermatitis. *Malassezia* overgrowth can provoke an overwhelming pruritic response in atopic dogs, which can occur acutely and be misconstrued as increased exposure to aeroallergens. Resolution of the yeast infection can reduce the pruritic threshold of an atopic dog by as much as 75% to 100% in some cases, depending on concurrent exposure to other allergens. Therefore undiagnosed MD is one of the most common reasons for perceived failure in the management of atopic dogs.

Malassezia pododermatitis may occur with or without more widespread MD. The feet are the most common single body area affected in allergic dogs. Patients with interdigital *Malassezia* pododermatitis are presented for the

complaint of paw licking/chewing. Paronychia (inflammation of the claw beds) may also occur as the sole presenting sign of MD and often causes claw biting. Physical examination usually reveals a reddish-brown staining of the proximal claw or a waxy exudate in the claw fold, with inflammation of the surrounding soft tissue.

In any dog with a known endocrine or metabolic disease, MD must be ruled out (by surface cytology) if pruritus, cutaneous inflammation, or even noninflammatory seborrhea are present.

Malassezia yeast also play an important role in cases of ceruminous otitis externa, in which they are highly proinflammatory. Some cases appear to be primary and associated only with moisture trapping (especially in swimming dogs).

DIAGNOSIS

Diagnosis of MD and MO is made by microscopic examination of surface cytology specimens. Diagnosis of MH in dogs is made by intradermal testing with a commercial *M. pachydermatis* extract.

Cytology

Because of its unipolar budding process, *M. pachydermatis* appears as oval, peanut, or bowling pin-shaped organisms cytologically (depending on the state of budding), with sizes ranging from 2 to 2.5×4 to $5 \mu\text{m}$ (Gueho, Midgley, and Guillot, 1996). Although this is the species most commonly isolated from normal and inflamed skin of dogs and cats, occasionally other species are identified. *Malassezia globosa*, which is sometimes associated with ceruminous otitis of cats (and less commonly in dogs), has a more spherical shape with tiny budding “heads.” Methods for collection include dry skin scrapings, adhesive tape stripping, cotton-tipped swabs, and direct impression smears with glass slides.

For dry skin, scrapings and adhesive tape stripping (or direct skin impression with adhesive-coated slides [Duro-Tak, Dermatologic Lab & Supply] work best. Clear adhesive tape (Scotch Tear-By-Hand Tape, 3M), which is my favorite method, works well in tight spaces and is very economical. The slide or adhesive tape should be applied to the area of interest two to three times in succession. Impression smears and tape stripping allow quantification of yeast per each microscopic field. With scrapings it may be necessary to mix the material with saline and heat fix until dry (to adhere the material to the slide). For greasy skin direct impression smears (without adhesive) often work better. For paronychia (inflammation of the claw bed) a cotton-tipped swab, the broken end of its wooden handle, or a metal spatula is used to scrape the claw fold; exudate is pressed or rolled firmly onto a glass slide.

For examination of ear exudate in dogs with ceruminous or exudative otitis externa, rolling exudate in a thin layer on glass slides with a cotton-tipped swab is the preferred method. It is often useful to sample the skin of the concave pinna separately from the ear canal if pinnal dermatitis is present.

Preparing Samples for Microscopic Examination

When material is applied to a glass slide, a modified Wright's stain (such as Diff-Quik) is used. Heat fixing the slide before

staining is performed by many dermatologists, but a study has shown it generally to be unnecessary. When adhesive tape is used, it may be dipped in the final stain only (no need to use a fixative), rinsed, and dried with a warm air dryer. The tape is applied to a glass slide while it is still warm and sticky for best adhesion. Some clinicians prefer wet mounts: a drop of new methylene blue stain is placed on a glass slide, and the tape strip is laid on top.

Cytologies should be examined under oil immersion (1000×) or high-dry (400×) for oval or budding yeast. I prefer oil immersion for more reliable identification of bacteria and yeast cells.

Interpretation of Cytologic Results: How Many Is Too Many?

For skin, 1 yeast per high-power (1000×) oil immersion field (hpoif) is a general guideline used by many dermatologists. For ear canals a study semiquantitatively evaluated the expected (commensal) populations of *Malassezia* spp. yeast residing in normal and diseased canals. It showed that normal dogs may routinely exhibit up to 5 organisms per high-dry (400×) field (roughly equivalent to ≤2 per hpoif), whereas cats may harbor up to 12 organisms per high-power dry field (roughly ≤5 per hpoif) (Ginel, 2002).

These numbers are guidelines only. Since dogs may mount a hypersensitivity response to *M. pachydermatis*, some individuals may suffer a pathologic effect from what would otherwise be considered a normal population of yeast colonizing the skin or ear canals. For example, a study examining yeast numbers on healthy and atopic canine skin suggested that 1 yeast per 27 hpoif may be sufficient to correlate with hypersensitivity (Morris, 1998). Since a threshold this low is almost impossible to quantify and appreciate clinically during routine practice, *I generally recommend antifungal chemotherapy when more than 1 yeast per 5 hpoif is identified on inflamed skin or more than 1 yeast per hpoif is identified from swabs of an inflamed ear canal.*

Intradermal Testing for *Malassezia* Hypersensitivity

A commercial *M. pachydermatis* extract is available for intradermal testing and subcutaneous immunotherapy

(Greer Laboratories). This allergenic extract is available in 20,000 protein nitrogen units (pnu)/ml and 40,000pnu/ml concentrations. A study conducted in healthy dogs with normal skin and dogs with AD (both with and without overt MD based on cytologic evaluation) has demonstrated a threshold concentration of 1000pnu/ml for use in intradermal testing (Farver et al., 2005). The threshold concentration of an allergen is that to which 90% of the nonallergic population is nonreactive (i.e., ceases to develop an irritant reaction). Ideally the threshold concentration also should correctly identify at least 90% of sensitized individuals, although this is difficult to assess because of lack of a validated gold standard. This extract is now included in the battery of allergens used for intradermal testing in my group practice for evaluation of dogs with a clinical diagnosis of AD.

To date a validated in vitro commercial assay for anti-*Malassezia* immunoglobulin E has not been reported in the scientific literature. Because of great discrepancies in results reported by research laboratories, any commercial offering of an enzyme-linked immunosorbent assay for detection of anti-*Malassezia* antibodies in canine serum should be scrutinized carefully by sound scientific methods before it can be recommended for routine use.

TREATMENT

The antifungal regimen chosen for therapy of MD or MO should be based on the distribution of the infection, the general health status of the patient, and expectations of the pet owner concerning time and effort commitment (relevant to topical therapy) and side effects (most relevant to systemic therapy). Diagnosing and eliminating (or controlling) underlying diseases are also paramount to long-term prevention of recurrence. Since *M. pachydermatis* is part of the normal cutaneous microflora, complete elimination of the organism is likely to be impossible.

Systemic Therapy (Table 104-1)

Unless there is a specific contraindication to using an oral antifungal drug, I prefer to treat all cases of

Table 104-1

Systemic Drugs for Treatment of *Malassezia* Dermatitis and Otitis Media

Drug	Supplied As	Dose/Frequency/Duration	Species
Ketoconazole	200-mg tablets	5-10 mg/kg qd × 21-28 days, or (low-dose regimen) 5 mg/kg qd × 10 days, then eod × 10 Pulse dosage regimen for <i>prophylaxis</i> : 5-10 mg/kg 2 consecutive days/week	D D
Itraconazole	100-mg capsules or 10 mg/ml elixir	5 mg/kg qd × 21-28 days, or 5 mg/kg 2 days/week × 3 weeks	D and C
Fluconazole	50-, 100-, 150-, 200-mg tablets and oral powder for 10 mg/ml suspension	2.5-5 mg/kg qd × 21-28 days	D and C
Terbinafine	200-mg tablets	30 mg/kg qd × 21-28 days 30-40 mg/kg qd × 21-28 days	D C

generalized and regional MD (e.g., pododermatitis) systemically. Otitis media also requires systemic therapy to (assumedly) achieve therapeutic drug levels within the tympanic cavity. Oral ketoconazole, itraconazole, or fluconazole is most commonly recommended. Griseofulvin is ineffective against *Malassezia* spp.

Ketoconazole (Nizoral, Janssen; and generics) is an imidazole antifungal with proven efficacy for canine MD. It undergoes extensive metabolism by the liver, and its use in patients with hepatic disease is contraindicated. It is also a known teratogen in dogs. Adverse effects include gastrointestinal upset (anorexia, vomiting, diarrhea), thrombocytopenia (rare), and hepatotoxicity, although none of these side effects is at all common. However, hepatotoxicity is a moderate risk in cats, and its use in feline MD is not recommended. In aged or debilitated dogs, liver enzymes should be evaluated before use of ketoconazole. I do not routinely perform screening tests in young/healthy dogs. For long-term or repeated use, monitoring of hepatic function is performed on a case-by-case basis as dictated by clinical signs (some dermatologists recommend monthly monitoring). This drug should always be administered with food for maximum absorption.

Itraconazole (Sporanox, Ortho Biotech) and **fluconazole** (Diflucan, Roerig; and generics) are triazole antifungals with less risk for hepatotoxicity than ketoconazole. Itraconazole is metabolized by the liver, whereas fluconazole is excreted via the kidneys. Because of cost, fluconazole is rarely chosen as a first-line treatment. Itraconazole is the treatment of choice in cats unless preexisting hepatopathy is known, in which case fluconazole should be used. Itraconazole should always be administered with food, whereas feeding does not influence the absorption of fluconazole.

Terbinafine (Lamisil, Novartis; and generics) is an allylamine antifungal with a high margin of safety for use in mammals. It is a less proven drug for MD but, based on its ability to reduce *Malassezia* colonization on healthy basenji hounds, it is likely to be effective.

Lufenuron (Program, Novartis Animal Health) is a benzoylphenylurea drug that disrupts chitin synthesis in the cell wall of insects and perhaps some fungi. There is no evidence at this time to suggest that this drug is effective in the treatment of MD.

Topical Therapy

Topical antifungals are most useful for treatment of localized infections or as adjunctive therapy along with oral drugs. Topicals are also quite valuable in the prophylaxis of chronic or relapsing MD.

For regional or generalized disease, shampoos containing miconazole, ketoconazole, chlorhexidine, or selenium sulfide are available and have met with variable success, depending on client compliance, frequency and technique of application, and severity of disease. For frequently relapsing cases, shampoo therapy (once to twice weekly, 10 minutes' minimum contact time) may be adequate for prophylaxis. Leave-on conditioners containing miconazole or chlorhexidine are also available and

provide for more residual action than shampoos. Rinses such as lime sulfur dip and enilconazole can be quite effective; however, lime sulfur dip is not available in the United Kingdom; enilconazole is available in Canada but not in the United States.

Miconazole, clotrimazole, or ketoconazole sprays, lotions, wipes, or creams may be used for "spot" therapy of the skin. Ointments and lotions containing nystatin, thiabendazole, miconazole, or clotrimazole are commonly used for otitis externa. Some products also contain glucocorticoids and antibacterials. An in vitro study comparing the efficacy of the azoles against *Malassezia* spp. yeast indicated that thiabendazole is the least effective, followed by clotrimazole (with efficacy comparable to nystatin), miconazole (with 10 times the potency of nystatin), ketoconazole, and itraconazole (Lorenzini, Mercantini, and De Bernardis, 1985). My clinical bias is that miconazole is the most effective topical therapy on a per-case basis, and poor clinical responses to nystatin, thiabendazole and clotrimazole have been common in my practice population.

Immunotherapy for *Malassezia* Hypersensitivity

The *M. pachydermatis* extract produced by Greer Laboratories has been evaluated in a multicenter study to determine its use as an immunotherapeutic extract. Atopic dogs that had been on allergen-specific immunotherapy for a minimum of 12 months but that continued to have chronic/recurrent MD and required antifungal prophylaxis were enrolled. A total dosage of 1000 pnu was administered weekly by subcutaneous injection, and cases were followed for 12 months. Although data from all member study sites have not been collated, it is clear from four cases enrolled at my practice that it can be effective. Two of four dogs had an excellent response with resolution of pruritus, discontinuation of maintenance antifungal therapy, and negative cytology, whereas the other two improved enough that the owners elected to continue with immunotherapy. Personal communication with clinicians at other study sites (A. Yu, Guelph, Ontario, Canada; L. Sauber, Tulsa, OK) suggests that this has also been the case elsewhere.

CHAPTER 105

Treatment of Dermatophytosis

DOUGLAS J. DeBOER, *Madison, Wisconsin*
KAREN A. MORIELLO, *Madison, Wisconsin*

Dermatophytosis is a zoonotic disease caused by infection of the dead, keratinized portions of cutaneous tissues (hairs, claws, and/or stratum corneum) with a superficial fungus adapted to living on the skin. Approximately 90% of feline dermatophytosis is caused by *Microsporum canis*; dogs may be infected with *M. canis*, *M. gypseum*, or *Trichophyton mentagrophytes*. Recently cats infected with alternate species such as *Microsporum persicolor* or *Trichophyton* spp. have been reported. For an infection to become established, there must be contact with another infected animal or a contaminated environment, often coupled with some predisposing host factor such as youth, debilitating disease, compromised immunologic status, or poor husbandry.

Dermatophytosis is more common in cats than in dogs. The disease may be pruritic or nonpruritic. Hair loss, scaling, and crusting are common clinical findings. In cats the disease can mimic almost any reported skin disease or reaction pattern. The disease can even mimic pemphigus foliaceus; therefore fungal cultures should always be part of the core diagnostic evaluation of any cat with skin disease. Rarely long-haired cats can develop a subcutaneous nodular form of the disease called *pseudomycetoma*. In dogs what is often diagnosed as dermatophytosis is the typical circular lesions of bacterial pyoderma. Dermatophytic *kerion reactions* appear as nodular-to-draining lesions that may mimic deep bacterial pyoderma. Infections in both dogs and cats can be very subtle, with lesions easily missed. This is most common in long-haired cats and long-haired small dogs, especially Yorkshire terrier dogs.

IMPORTANT POINTS TO REMEMBER ABOUT DIAGNOSTIC TESTS

Role of the Wood's Lamp, Direct Examination, and Biopsy

Wood's lamp (ultraviolet lamp) examination is a reasonable screening tool for *M. canis* infection, but a positive

test is not diagnostic. It is most useful in animals with lesions to identify potentially infected hairs for culture or for direct examination. The fluorescence must be *bright "apple green"* and located along the hair shafts to be considered suspicious. Direct microscopic examination of hairs can confirm the presence of an infection. Examination of hairs for ectothrix spores is recommended only with Wood's lamp-positive hairs and if the clinician or technician has some expertise. Clearing agents or mineral oil can be used to examine hairs. Suspected fluorescing hairs or hairs with apparent ectothrix spores must be cultured to confirm presence of dermatophyte infection. It is rarely necessary to resort to a skin biopsy for diagnosis. Exceptions to this include confirmation of fungal kerion reactions or pseudomycetoma.

Fungal Culture

The standard of care for diagnosis or confirmation of infection is a fungal culture. Many commercial fungal culture media are available; work by one of the authors (KAM) has found little difference among routinely available media, provided that the culture plate has sufficient depth of medium to avoid premature drying. On a conventional 10-cm Petri dish, at least 15 ml of medium is necessary, and more if possible. Cultures should be incubated between 24° and 30 °C (75° and 86°F); inexpensive digital aquarium thermometers can be used to ensure this temperature. Cultures incubated at lower temperatures (e.g., 18 °C or 65 °F) may not sporulate, or sporulation may be delayed by up to 10 days. The most widely used fungal culture medium is dermatophyte test medium (DTM), which contains inhibitors of bacterial and saprophyte growth and a color indicator. A toothbrush is ideal for obtaining a culture sample from most animals; the technique has been widely described. Animals with large amounts of debris on the hair coat should be wiped with a cloth first. If culture of the environment is desired, it can be sampled using small squares of Swiffer (Procter & Gamble)

cloths brushed across the contaminated areas. Daily visual examination of inoculated plates allows for rapid identification of highly suspicious colonies. Suspect pathogenic colonies are pale or white with a red ring of color developing around them as they grow on DTM. Microscopic confirmation is required because some nonpathogenic fungi can turn DTM red immediately and all saprophytic fungi will eventually cause a red color change given sufficient time. Once the medium has turned completely red, the usefulness of the color indicator is lost. Microscopic examination is not difficult. The preferred fungal stain is lactophenol cotton blue; new methylene blue stain can also be used. Clear or frosted acetate tape is used to sample the colony by brushing the sticky side lightly across it. Clear tape is placed sticky side down over a drop of stain on a microscope slide; frosted tape is placed sticky side up on the slide. In either case a second drop of stain is placed on top of the tape followed by a glass coverslip. Examine at 100× and 400× total magnification. The reader is referred to a mycology textbook or websites such as www.doctorfungus.com for additional information on identification of microscopic colonies. If dermatophyte colonies are not confirmed, it is important to be sure that the culture has been incubated at an appropriate temperature and wait 1 to 4 more days before resampling. In some cases subculturing may be needed. Most pathogens grow within 7 to 10 days; however, cultures from animals undergoing treatment should be held for 21 days because treatment slows growth of cultures.

TREATMENT PRINCIPLES AND OPTIONS

In most healthy animals dermatophytosis is a self-curing disease and eventually (in weeks to months) will resolve spontaneously. However, this zoonotic disease *should* always be treated to shorten the course of infection and minimize the chances of transmission to other animals or humans. The best treatment protocol is a combination of three elements: *environmental treatment*, *adjunct topical treatment*, and *systemic treatment*. Newer drugs coupled with increasing clinical studies on this disease now allow veterinarians to offer a variety of effective treatment options to clients.

Limiting and Controlling Contamination of the Environment

Limiting spread of the disease in the environment is often the last point discussed with clients. However, we recommend *starting* treatment discussion with this point because it is then easier for clients to understand and comply with treatment recommendations. In any dermatophyte infection, infective hairs and spores are always shed into the environment. The severity of environmental contamination is related to the host species (cats shed more material than dogs), the severity of lesions, and the number of animals. Environmental contamination studies by one of the authors (KAM) have shown that the more the animal is allowed to roam in the home, the more widespread the contamination. Confinement of animals restricted dissemination of spores; reasonable cleaning of the home and the confinement area minimized spore contamination.

Once an infected animal was removed or cured, culture-positive homes could be returned to culture-negative status with appropriate cleaning procedures.

The key things owners can do to limit environmental contamination of the home (Box 105-1) include: (1) *confinement of the pet* to one room that can be cleaned easily twice weekly; (2) removal of infective hairs from the coat either by *clipping or bathing*; and (3) topical *whole body antifungal rinses*. Twice-weekly cleaning should include thorough vacuuming of the room, followed by use of Swiffer (Procter & Gamble) cloths to trap residual hairs and spores not collected by vacuuming. Also recommended are cleaning with a detergent safe for use on the surfaces in the room and use of a sporicidal disinfectant on nonporous surfaces. Pets should be provided with bedding (e.g., towels) that can be washed daily. Contamination is most severe in areas where the pet spends the most amount of time; thus these areas should receive special attention.

Many disinfectants labeled as effective for killing dermatophytes in the household or veterinary clinic are not practically effective for this purpose. Commercial disinfectants are tested for antifungal activity by observing their effects on suspensions of fungal spores or fungal mycelium in a test tube. However, in a house or a veterinary hospital the predominant contamination is not with spores or mycelium but rather with small fragments of infected hairs. It is possible that the hair shaft and associated organic debris protects the fungus from the actions of disinfectants. Studies that simulate actual conditions of use demonstrate that, of many different disinfectants tested, the only products that were safe and practical to use in the home were chlorine laundry bleach (sodium hypochlorite 5%) and enilconazole environmental spray. The latter is available and registered for animal facility use in some countries, including for use in ringworm-infested

Box 105-1

Recommended Environmental Control Measures in Treatment of Dermatophytosis

For Household Situations With One or a Few Animals

- Confine pets to easily cleaned room or rooms.
- Thoroughly vacuum floors and furniture (removes many infected hairs and spores). Discard or empty vacuum cleaner bag.
- Wash hard floor and other contact surfaces with detergent and water.
- Dust other surfaces with Swiffer cloths to remove spores.
- Launder (hot water wash and hot dryer) area rugs, animal bedding, and bed linens if pet is allowed on furniture.
- Launder, disinfect, or discard pet toys and grooming aids.
- If possible, carefully disinfect hard-floor surfacing with 1:128 bleach solution; allow 10 minutes' wetting time.
- Vacuum (and disinfect if possible) any vehicles and transport cages used for animals.
- Repeat cleaning and disinfection twice weekly.
- After cure or removal of animal, culture areas for contamination by wiping small squares of Swiffer cloths over exposed areas and inoculating soiled surface of cloth onto fungal culture plate.

animal shelters. In North America it is registered only for use in poultry house *Aspergillus* disinfection (Clinafarm, Sterwin). For bleach disinfection, the higher the concentration, the better the effectiveness; but the solution is also highly corrosive and toxic and damages carpets and fabrics. Bleach also is irritating to the mucous membranes of pets and humans. We find that a reasonable compromise is a 1:128 dilution of household chlorine laundry bleach (1 oz of bleach per gallon of water) that is sprayed on targeted surfaces after initial cleaning. It is important to note that a contact time of 10 minutes is needed. This concentration is effectively fungicidal yet not too overpowering for the owner to use. The owner should be advised to wear protective clothing and eyewear, and good ventilation should be provided for both the pets and people. It is most safely applied using a small spray bottle that allows for direct and controlled application.

Clipping of the Hair Coat

Removing infected hairs by clipping reduces the quantity of infective spores that could contaminate the environment, spread the infection to other animals, or spread the infection to other areas on the same animal. However, clipping the hair coat can temporarily worsen the infection by mechanical spread of the spores and microtrauma to the skin. Electric clippers are contaminated in the process, as is the area where the clipping is performed, creating need for additional environmental decontamination. One of the authors (KAM) has been a strong proponent of clipping the hair coat but, after encountering many situations in which clipping the hair coat resulted in “clipper burn” or true thermal burns to the patient, now advocates a more restrained case-by-case consideration. Whole-body clipping is advisable in long-haired cats and long-haired dogs, especially if they have failed therapy or are clinically recovered but still culture positive. Many pet animals are presented early in the disease state when it may be possible to clip hairs from around lesions gently with scissors or pluck individual glowing hairs, making whole-body clipping unnecessary. Mechanical removal of infected hairs is facilitated by bathing and combing

the hair coat to remove loose hairs. If a glowing strain of *M. canis* is present, another strategy can be used: initiating antifungal therapy, allowing the hairs to grow out for a week or so, and then scissor-clipping the glowing tips of infected hairs.

Adjunct Topical Treatments

The goal of adjunct topical therapy is to help shorten the course of infection and limit the spread of infective material to people, other animals, and the environment. Localized topical therapy (“spot-treatment”) with creams, lotions, and ointments is *not recommended* because subclinical areas of infection will be missed or induced. Whole-body treatment with an antifungal rinse or shampoo is strongly recommended. Various studies have shown that lime sulfur, enilconazole, and miconazole are effectively antifungal (Sparkes et al., 2000). Miconazole or ketoconazole plus chlorhexidine shampoos or rinses (Malaseb, DVM Pharmaceuticals; KetoChlor, Virbac) are more effective than the single ingredients; the combination of an azole drug and chlorhexidine is synergistic (Perrins and Bond, 2003). Currently favored topical whole-body rinses for dermatophytosis are summarized in Table 105-1. Lime sulfur solution is safe even for kittens or puppies as young as 1 week of age, although it is odiferous. Enilconazole (Imaverol, Janssen) is a topical antifungal rinse licensed in many countries (but not the United States) for dogs and horses. It has been used on cats (an off-label use; Hnilica and Medleau, 2002); some clinicians advocate the use of an Elizabethan collar after each rinse until the coat is dry, thus preventing ingestion of the solution.

Although controlled comparative studies are not available, we believe that lime-sulfur or enilconazole rinses are the most effective adjunct topical treatments; however, their disadvantages (odor, unavailability) may limit their use in some situations. A second-choice topical regimen is miconazole-chlorhexidine rinse after shampooing used twice weekly. Isolated infective spore studies have shown that this rinse is equally sporicidal as lime sulfur; however, in field studies animals treated with lime sulfur cured faster than animals treated with the miconazole-chlorhexidine rinse.

Table 105-1

Summary of Recommended Adjunct Topical Products for Treatment of Dermatophytosis in Dogs or Cats

Treatment	Usage and Comments
Lime-sulfur rinse (sulfurated lime solution)	Per label, dilute in water at 4-8 oz/gallon (1:16 to 1:32 dilution); shake well before each use. Saturate entire hair coat by sponging or spraying twice weekly. Do not rinse, towel dry. May stain jewelry, light hair coats, or porous surfaces.
Enilconazole topical rinse (Imaverol)	Per label, dilute in water to a 0.2% solution. Apply as for lime sulfur, twice weekly. If used on cats, place Elizabethan collar until hair coat is dry. Not available in United States.
Miconazole-chlorhexidine rinse (Malaseb Concentrate Rinse)	Per label, dilute in water at 1 oz/quart. Apply as for lime sulfur, twice weekly. Efficacy is not as well established as for lime sulfur or enilconazole but is widely available and odor free.
Antifungal shampoos: Miconazole-chlorhexidine (Malaseb) Ketoconazole-chlorhexidine (KetoChlor)	Optional treatment; does not replace use of whole-body rinses above. Use twice weekly before antifungal rinse.

Whole-body rinses are easily applied using a garden watering can or small pressurized tank-type garden sprayer. It is important to apply the solution close to the skin and soak the hairs and skin thoroughly. The solution should not be rinsed from the coat; the animal should be towel dried.

Systemic Treatment Options

After discussing methods for limiting the spread of infective spores into the environment, deciding whether or not the hair coat or lesions will be clipped, and what adjunct topical therapy will be used, a systemic antifungal drug should be selected (Table 105-2). It is important to remember that dermatophytosis is an intrafollicular disease and that systemic treatment is responsible for actually shortening the course of infection in the individual animal.

Griseofulvin

Griseofulvin is becoming difficult to obtain and is being used less and less often. However, if it can be obtained, nearly all feline and canine patients with *Microsporum* infections and most with *Trichophyton* infections are cured by this drug. Griseofulvin is highly teratogenic and *must not be used in pregnant animals!* In cats bone marrow suppression is a severe and unpredictable side effect. It is not dependent on dose, breed, or length of therapy. Blood counts (especially white blood cell) are recommended *at least* monthly (some clinicians recommend every 1 to 2 weeks) when using this drug in cats. Cats should be tested for feline leukemia virus and feline immunodeficiency virus infection before use since there may be an association between infection and these adverse reactions. In one controlled study griseofulvin therapy alone required a mean of 70 days of treatment to cure experimentally infected cats (Moriello and DeBoer, 1995). Because of the pharmacokinetics of this drug, it is not suitable for pulse-therapy options. We do not recommend griseofulvin as a first choice in cats. In large dogs it may be more cost effective. *The dose is dependent on the formulation (microsize versus ultramicrosize).*

It is critically important to determine the exact preparation one is prescribing to prevent potentially lethal dosages of griseofulvin. Absorption is enhanced with a fatty meal. Vomiting, diarrhea, and inappetence are common adverse effects.

Ketoconazole

The true clinical efficacy of ketoconazole in dermatophytosis is unknown; there are limited anecdotal reports on its efficacy. Some strains of *M. canis* are resistant to ketoconazole. The drug is not well tolerated in cats and is not recommended for use in this species. Studies suggest a high prevalence (≈25%) of hepatotoxicity in cats and occasionally at higher doses in dogs. Ketoconazole as a systemic antifungal is best reserved for infections in dogs, particularly *Trichophyton*. Ketoconazole has become inexpensive over the past few years, but other than this it has no advantage over other drugs in routine cases of dermatophytosis.

Itraconazole

In many areas of the world itraconazole is currently the most commonly used drug for the treatment of dermatophytosis in both dogs and cats. Itraconazole (Sporanox capsules or oral solution, Janssen) is a triazole antifungal that accumulates and persists in hair and epidermis dermatophytosis in pulse-therapy protocols. These schedules are easier for owners and more cost effective. In countries where itraconazole is licensed for veterinary use, the official label directions are 5 mg/kg once daily PO. Treatment is initiated with three “pulses” of 1 week on, 1 week off (i.e., 3 weeks of drug administration out of a total treatment length of 6 weeks). In working with infected catteries and shelters, one of the authors (KAM) has noted occasional need for higher dosages (up to 10mg/kg/day) and/or need for daily (not pulsed) treatment in some cats before mycologic cure can be obtained. Pulse therapy is not ideal for animals that are ill or have limited body fat because the drug is stored in body fat. An alternative protocol that I have used is 21 to 28 days of once-daily treatment; it is important to note that this protocol is only recommended if adjunct topical therapy with lime sulfur is used.

Table 105-2	
Summary of Recommended Systemic Products for Treatment of Dermatophytosis in Dogs or Cats	
Treatment	Usage and Comments
Griseofulvin	Dogs or cats, effective but difficult to obtain; ultramicrosize form recommended if available; 5-10 mg/kg once daily or divided PO; for microsize form, 25-50 mg/kg once daily or divided PO; teratogenic; possible myelotoxicity in cats, monitor white blood cell counts
Ketoconazole	For use in dogs only; hepatotoxic in cats; may be useful for <i>Trichophyton</i> infections; less certain for <i>Microsporum</i> ; 5-10 mg/kg once daily PO; inexpensive generic available in United States
Itraconazole (Sporanox or Itrafungol)	Dogs or cats; systemic drug of choice, but cost may limit its use to cats or small dogs; 5-10 mg/kg once daily PO on alternate weeks (e.g., administer for 7 days, then skip treatment for 7 days); manufacturer recommendation is 5 mg/kg/day, but we find occasional animals (especially stressed or ill animals in shelter situations) that clear very slowly on this dosage and require the higher dosage and/or continuous daily treatment
Terbinafine (Lamisil)	Most reported use is in cats for apparently azole-resistant infections; limited experience in dogs; very expensive; feline dosage: 30-40 mg/kg once daily PO; optimal canine dosage not established; possibly hepatotoxic, monitor liver enzymes

For cats the 100-mg capsules can be divided into smaller doses manually and repackaged in empty gelatin capsules or mixed with a small amount of food; alternatively one can use the 10-mg/ml oral solution. Both are marketed in North America for human use; the oral solution is marketed for cats in Europe (Itrafungol, Janssen). Toxicity problems are rare to nonexistent with this protocol, even in cats. As a note of caution, we are aware that some owners have obtained bulk itraconazole powder inexpensively in foreign countries, and anecdotally this treatment often fails. Itraconazole requires careful formulation in appropriate vehicles to ensure its absorption, and use of any material other than the “official” approved products is not recommended because it may result in treatment failure.

Fluconazole or Terbinafine

Fluconazole has received some recent attention from cattery breeders as an alternative drug. It is not well studied for animal use, and recent studies indicate that it is probably less active against animal dermatophytes than itraconazole. Current evidence and clinical anecdotes suggest that there is no advantage of this drug over the “more proven” itraconazole. Oral terbinafine (Lamisil, Novartis) in initial studies also seems to be effective in some situations. Again, this drug is much less studied, is very expensive, and currently appears to offer no advantages over itraconazole. Cats with *M. canis* infections apparently resistant to azole drugs can sometimes be treated successfully with terbinafine. Various dosages have been used (10 to 40 mg/kg once daily PO), but cats treated at the higher end of the dosage range cure significantly faster. Liver enzymes should be monitored; this drug may elevate ALT in cats, although no clinical toxicity is necessarily seen. We frequently see requests from owners for “the newest and best wonder drug” to eradicate an infection. However, it is important to note that systemic drug selection is invariably the *least* prevalent reason why control of an infection has failed!

Lufenuron

A published case series (Ben-Ziony and Arzi, 2000) caused speculation that lufenuron (Program, Novartis) may be beneficial in treatment of feline or canine dermatophytosis. Although there have been anecdotal reports of “cures” from lufenuron, controlled studies have shown consistently that lufenuron is ineffective as both a treatment and preventive drug. In controlled studies using feline experimental infection models (DeBoer et al., 2006), lufenuron did not prevent initial establishment of ringworm in cats, did not result in faster cure once the infections were established, and was not synergistic with terbinafine. With wide

availability of proven, effective treatments for this zoonotic disease, we do not recommend use of lufenuron.

Endpoint of Therapy

Regardless of the combination of topical and systemic treatments selected, all infected animals should be treated until at least two negative fungal cultures are obtained 1 to 2 weeks apart. Toward the end of treatment, when visible lesions may no longer be present, sampling of the entire hair coat with the toothbrush method is greatly preferred. One of the authors (KAM) is a strong advocate of weekly fungal cultures to monitor response to therapy.

Treatment of Catteries and Animal Shelters

It is not within the scope of this chapter to discuss eradication of dermatophytosis from catteries and animal shelters. Such treatment involves many important details, and the reader is referred to the reading list for more information and complete treatment protocols (Moriello and Newbury, 2006). With respect to animal shelters, the reader is also encouraged to contact a regional veterinary school that has an active shelter medicine program.

Nonneoplastic Nodular Histiocytic Diseases of the Skin

VERENA K. AFFOLTER, *Davis, California*

CATHERINE A. OUTERBRIDGE, *Davis, California*

Histiocytes include macrophages and dendritic antigen-presenting cells, both of which have different tissue distribution and function (see also Chapter 75). Macrophages are primarily involved with phagocytosis and intracellular digestion of foreign antigens, whereas dendritic antigen-presenting cells are poorly phagocytic but are specialized in processing and presenting antigens. Macrophages and dendritic cells cannot reliably be differentiated based on light microscopic features. However, they express different leukocyte antigens, which can be identified by immunohistochemistry on fresh, snap-frozen tissue.

Nodular granulomatous and pyogranulomatous dermatitis are of either infectious or sterile origin (Box 106-1). These lesions are characterized by numerous macrophages and dendritic cells accompanied by various numbers of neutrophils and lymphocytes. Canine

reactive histiocytosis of dendritic cell origin may be limited to the skin—cutaneous histiocytosis—or affect skin and other organ systems (systemic histiocytosis). Canine reactive histiocytosis is discussed in detail in Chapter 75 together with the other proliferative histiocytic diseases, including canine cutaneous histiocytoma, Langerhans cell histiocytosis in dogs, and progressive histiocytosis in cats. Chapter 75 also discusses the histiocytic sarcomas of dendritic cell or macrophage origin.

This chapter focuses on the discussion of other non-infectious nodular skin diseases that are largely predominated by histiocytes (often referred to as histiocytic and/or granulomatous dermatitis). The diseases discussed include cutaneous xanthoma, foreign body reaction, palisading granuloma, canine sarcoidosis, and reactive fibrohistiocytic nodules.

Nodular granulomatous and histiocytic skin lesions may present with similar clinical features and can mimic cutaneous neoplasia or follicular cysts. Histopathology is required to achieve the correct diagnosis. Special stains, immunohistochemical evaluation (bacillus Calmette-Guérin stains), cultures, and polymerase chain reactions for identification of bacterial and fungal elements assist to rule out possible lesional infectious pathogens. However, the differentiation between macrophages and dendritic cells can only be achieved by immunohistochemistry on fresh, snap-frozen tissue (see previous paragraphs).

Box 106-1

Nodular to Diffuse Granulomatous and Pyogranulomatous Dermatitis of Infectious and Noninfectious Etiology in Dogs and Cats

Infectious Etiology	Noninfectious etiology
Actinomycosis and nocardiosis	Sterile granuloma and pyogranuloma syndrome
Bacterial pseudomycetoma	Reactive histiocytosis*
Feline leprosy syndrome	Palisading granuloma*
Canine leproid granuloma	Cutaneous xanthoma*
Opportunistic mycobacterial infections	Canine sarcoidosis*
Dermatophyte pseudomycetoma	Foreign body reaction*
Cutaneous blastomycosis, coccidioidomycosis, histoplasmosis	Juvenile sterile granulomatous dermatitis and lymphadenitis
Cryptococcosis	Granulomatous drug reaction
Sporotrichosis	
Opportunistic fungal infections	
Pythiosis, lagenidiosis, entomophthoromycosis	
Protothecosis	
Leishmaniosis	

*Sterile lesions predominated by histiocytes are discussed in this chapter. From Gross TL et al: *Skin diseases of the dog and cat: clinical and histopathologic diagnosis*, ed 2, Oxford, 2005, Blackwell Publishing, p 320.

CUTANEOUS XANTHOMA

Etiology and Pathogenesis

Cutaneous xanthomas (xanthomatosis) are granulomatous skin lesions containing deposits of lipoprotein. In general, lipoproteins deposits occur secondary to elevated serum lipid levels induced by dyslipoproteinemias, usually a hyperlipidemia, hyperlipoproteinemia, or hypercholesterinemia. These lipid disturbances may be inherited (primary) or acquired (secondary). Exact mechanisms inducing lipid depositions in tissues in dogs and cats with a lipid metabolism disturbance are not known. Trauma has been suggested as a triggering factor. *Cats with primary disorders of lipid metabolism* present with exacerbation of any clinical signs if fed a fat-laden diet. Depending on the type of lipid disorder, cats may have elevated fasting triglycerides, cholesterol, or low-density lipoproteins (LDLs). Interestingly, cats with familial lipoprotein lipase (LDL) deficiency do not tend to develop xanthomas. Primary

hypercholesterolemia is most commonly associated with the development of xanthomas. *Cats with secondary disorders of lipid metabolism* most commonly present with xanthomas as a result of megestrol acetate–induced diabetes mellitus with associated hypertriglyceridemia. A decreased LPL activity from insulin deficiency was documented in one cat. Alternatively, prolonged corticosteroid administration may result in hyperlipoproteinemia and thus may have contributed in a case of feline xanthomas and arteriosclerosis. *Xanthomas in dogs* have been reported in association with secondary disorders of lipid metabolism such as high cholesterol diet and hypertriglyceridemia with or without associated diabetes mellitus.

Clinical Features

Cutaneous xanthomas are rare in the cat and very rare in the dog. No breed or sex predilection is known. *In cats* pale, yellow-to-white, occasionally brown papules, nodules, or plaques are typically seen. The lesions tend to be friable and may have an erythematous border. Minor trauma often results in hemorrhage. The lesions are mostly found on the head—in particular symmetrically in the preauricular area and the pinna. Other locations are bony prominences on the legs and also on paw pads. *In dogs* yellow papules and nodules may develop in various locations. Face, ears, neck, legs and feet, tail, and ventrum are the most common sites. Fasting 24-hour lipid profiles and lipoprotein electrophoresis to evaluate for changes in triglycerides, cholesterol, and lipoproteins assist in making the diagnosis of xanthomas.

Histopathology

Sampling of ulcerated and traumatized lesions should be avoided since hemorrhage and secondary inflammation may be the overwhelming histologic features. Typically the normal tissue is disrupted by a nodular-to-diffuse infiltrate of large foamy histiocytes consistent with macrophages. The histiocytes may palisade along collagen bundles. Extracellular lakes of lipid, sometimes associated with cholesterol clefts, may separate the histiocytic infiltrate. Eosinophils are often present; whereas infiltration by lymphocytes, plasma cells, and neutrophils is less prominent.

Clinical Management

Dietary adjustments should be made, and the affected animal should be fed a low-fat and low-cholesterol diet since this hopefully will minimize the effects of a primary lipid disorder. If present, diabetes mellitus must be addressed as well, with appropriate management of the disease. Surgical removal of the skin nodules does not prevent development of new lesions but may ameliorate any discomfort from existing lesions.

FOREIGN BODY REACTIONS

Etiology and Pathogenesis

Penetrating foreign bodies commonly pass through the epidermis and eventually get trapped in the dermis,

panniculus, or the subcutis, inducing a granulomatous response (“foreign body granuloma”).

Exogenous Foreign Bodies

Some plant foreign bodies such as grass awns (foxtails, cactus spines, burdock burrs, seeds) and porcupine quills have regional distributions. Many foreign bodies occur worldwide (wood splinters, suture material, road gravel, fiberglass fibers, and air gun pellets). With exogenous foreign bodies it is not unusual to see secondary infectious processes, including bacterial infections (*Staphylococcus intermedius*, actinomycetes *Nocardia* spp., opportunistic mycobacteria, anaerobic bacteria), saprophytic or systemic fungal infections, dermatophytes, saprophytic water molds (*Pythium insidiosum* and *Lagenidium* spp., Chapter 274), and algae (*Prototheca* spp).

Endogenous Foreign Bodies

Free hair shaft keratin and keratin lamellae within the dermis secondary to furunculosis or traumatic follicular damage can elicit a marked inflammatory reaction. Altered extracellular matrix, including amyloid deposition or poorly defined collagen alterations secondary to degranulation and degradation of eosinophils (previously referred to as “collagenolysis”), can solicit a marked granulomatous response.

Clinical Features

Clinical signs may present with a lag period because the inflammatory reaction around the foreign body takes time to develop. Localized erythema and swelling is observed, which progresses into firm dermal and subcutaneous nodules or abscesses, with or without fistulation. Seropurulent or serosanguineous exudates and occasionally parts of the foreign material may extrude from the draining tract. Migration of pointed foreign bodies and barbed plant awns (such as foxtails) may be enhanced by muscular movement.

Dogs

Cutaneous and subcutaneous foreign body reactions are common in outdoor dogs, in particular in young hunting and working dogs. Plant foreign bodies are more commonly seen in long-coated breeds with a higher incidence in late summer and autumn. Sex predilections have not been noted. The external ear canal and dorsal interdigital webs are common locations for grass awn entry.

Cats

Except for entrapped plant material, foreign bodies are uncommon in cats. Effective grooming behavior may help to avoid the entrance of penetrating foreign bodies in this species.

Histopathology

The usually chronic inflammatory process involves deep dermis, subcutis, and possibly skeletal muscle. The center may be cavitated. With secondary infectious processes lesions may contain a marked suppurative inflammation. Typically numerous histiocytes are present. The central cavitation may include the foreign material, in which

case numerous large epithelioid macrophages palisade along the foreign material. In subacute-to-chronic lesions prominent fibrosis surrounds the process, and the periphery contains numerous plasma cells and lymphocytes. Occasionally there is a draining tract connecting the center of the lesions with the skin surface.

Clinical Management

Foreign bodies may have been eliminated via fistulation and formation of draining tracts. Subsequently the lesions heal. Secondary infectious processes have to be addressed with appropriate wound cleaning, drainage, and antibiotic therapy. Secondary endogenous foreign body reaction such as free hair shafts resulting from additional trauma may complicate the process and tend to cause persistent inflammatory response such as that seen in interdigital nodular pododermatitis.

PALISADING GRANULOMA

Etiology and Pathogenesis

Palisading granuloma can be observed in dogs. The exact etiology is unknown, but blunt trauma may be an initiating factor because many lesions occur over pressure points. Alternatively, local ischemia has been proposed as a triggering factor. The latter hypothesis is based on the description of a palisading granuloma in conjunction with an underlying arteriovenous malformation. Lesions resembling Churg-Strauss granuloma, a process associated with systemic immunoreactive or autoimmune diseases in humans, has been observed in a dog with altered secretion of antidiuretic hormone.

Clinical Features

Palisading granulomas are seen predominantly in larger-breed dogs. There is no sex or age predilection. Typically solitary dermal nodules are seen over pressure points such as zygomatic arch and hip or on the lips. Palisading granulomas also can develop on the tongue.

Histopathology

The nodules are located in the dermis and/or subcutis and may have an elongated shape. The diffuse granulomatous inflammation is composed of coalescing granulomas centered on collagen fibers, which often have an altered tinctorial, brightly eosinophilic appearance and are fragmented. A pale eosinophilic, amorphous material may encircle the collagen bundles; and numerous macrophages are aligned (i.e., palisade) along the collagen. Variable numbers of lymphocytes and plasma cells are present. If neutrophils are evident, they are usually observed in areas of cellular necrosis. The overlying epidermis is normal or atrophic.

Clinical Management

Palisading granulomas are most commonly solitary lesions, and surgical excision is curative.

REACTIVE FIBROHISTIOCYTIC NODULES

Etiology and Pathogenesis

The etiology of canine fibrohistiocytic nodules is unknown. This reflects the situation in humans. Various terms have been used to refer to this lesion: benign fibrous histiocytoma, juvenile xanthogranuloma, and fibroxanthoma. The exact origin of the histiocytic cells is not known, but the presence of lipid-type vacuoles in many of the lesional histiocytes suggests macrophage origin with phagocytic activity. The benign morphology of the histiocytes, presence of a mixed cell population, and biologic behavior suggest an inflammatory reactive process; but the possible triggering factor has not yet been identified.

Clinical Features

Canine reactive fibrohistiocytic nodules are uncommon and mostly affect dogs less than 3 years of age. The mostly solitary or occasionally multiple, firm cutaneous nodules measure less than 1 cm in diameter. They may be partially alopecic. Predilection sites are face, scrotum, and legs. There is no breed or sex predilection.

Histopathology

The nonencapsulated, wedge-shaped dermal nodules are predominated by a round-to-polygonal or plump spindle-shaped histiocytic infiltrate, which usually extends to the dermal-epidermal junction. The histiocytes contain variable numbers of delicate lipid vacuoles. The sparse collagenous matrix, which may be partially hyalinized, most likely represents residual dermal collagen. Mitotic figures are observed infrequently, and occasional multinucleated cells are present. Some elongated spindle cells consistent with fibrocytes may be interspersed with the histiocytes. Lymphocytes and fewer neutrophils and eosinophils may be present.

Clinical Management

Surgical excision is curative. Most reactive fibrohistiocytic nodules are solitary and diagnosed after surgical excision. Therefore it is not known if spontaneous regression occurs.

CANINE SARCOIDOSIS

Etiology and Pathogenesis

Sarcoidosis is a multisystemic granulomatous disorder of unknown etiology and has best been described in humans and horses. This disease mostly affects the skin, lungs, lymph nodes, and eyes. In humans an antigen-driven process supported by a CD4⁺ helper-inducer T cell (TH₁) milieu is suggested. Recently mycobacterial deoxyribonucleic acid was identified in some cases of human cutaneous sarcoidosis, but no infectious pathogens have been found in equine lesions. Lesions consistent with canine sarcoidosis have been seen only in the skin; infectious pathogens have not been identified.

Clinical Features

The following clinical observations are based on a small number of cases; and sex, age, or breed predilections are not known at this point. Erythematous papules, plaques, and nodules are observed. The lesions have been described on the trunk, neck, face, and ears. Pruritus or pain is not observed.

Histopathology

Lesions typically seen in sarcoidosis are referred to as *naked granulomas* since associated lymphoid infiltrates are sparse. The nodules are mostly in the superficial and middermis, but subcutaneous involvement has been described. Epithelioid histiocytes and variably vacuolated macrophages predominate the lesions with little or no marginal lymphocytic infiltrates. Neutrophils are rare.

Clinical Management

Based on the small numbers of cases observed, no information about clinical management is available. Corticosteroid therapy and antihistamine administration were successful in some horses with sarcoidosis.

CHAPTER 107

Diseases of the Anal Sac

RUSTY MUSE, *Tustin, California*

Diseases and abnormalities of the anal sac are common concerns faced by pet owners and the general practitioner. Unfortunately the volume of research, literature, and information available about anal sac disease does not correspond to the frequency with which these problems occur. Knowledge of normal anal sac structure and function, and an appreciation of the various disorders that can involve these tissues, is critical to successful management of anal sac diseases.

Anal sacs are paired invaginations of the skin located between the internal and external sphincters of the anus. Each sac is connected to the surface by a duct that opens at the mucocutaneous junction of the anus in the dog. The anal duct of cats opens onto a prominence just lateral to the anus. The anal sacs are lined with stratified squamous epithelial cells and contain large apocrine glands with smaller numbers of sebaceous glands. In addition, the walls of the anal sac are lined with elastic and smooth muscle fibers. The duct is lined with both apocrine glands and large sebaceous glands.

The anal sacs provide a reservoir for the secretions of these glands admixed with desquamated epithelial cells. This forms the brown, oily-to-waxy secretion that is normally

evacuated as a result of pressure from fecal excretions. However, change in character of the secretion or alteration in muscle tone or fecal form may cause overfilling and plugging of the sacs and resultant fermentation, inflammation, and infection. Because of the thinness of the anal sac and the ease with which it is normally evacuated, it is not distended in normal dogs. However, if enlarged, it can be palpated easily at the four and eight o'clock positions between the smooth muscle of the anal canal and the striated muscle of the external anal sphincter.

PHYSICAL CHARACTERISTICS

The normal characteristics of anal sac secretion and histologic evaluation have long been used to try to attempt to discern disease of the anal sac; however, these data also have been evaluated and reported only occasionally. Several recent studies have provided new sources of information regarding the gross, cytologic, and bacteriologic characteristics of normal anal sac secretions in the normal dog (Robson, Burton, and Lorimer, 2003; Lake et al., 2004) and in dogs with various dermatologic diseases (Pappalardo, Martino, and Noli, 2002).

Gross Characteristics

In one study (Robson, Burton, and Lorimer, 2003) the anal sac secretions in normal dogs were reported as a thin liquid exudate in 19 of 27 dogs, whereas 8 of 27 had either thick liquid or pasty discharge. Color of the discharge was reported as either light or dark brown in 21 of 27 dogs. Similar characteristics were noted between the right and left anal sac in most dogs (10 of 11 had similar consistency, whereas 9 of 11 had similar color). Another study (Lake et al., 2004) reported that of 41 pairs of anal sac evaluations in clinically normal dogs, the consistency of the discharge was reported as “watery” in 33 of 41 dogs in at least one of the sacs; however, the consistency was similar between the right and left sacs in only 18 of 41 dogs. Color of the discharge of one or both anal sacs in this study varied widely from creamy whitish-yellow in 15 of 41 dogs, grayish-tan in 13 of 41 dogs, orange-yellow in 11 of 41 dogs, and reddish-brown in 10 of 41 dogs. In another study that evaluated anal sac secretions in normal dogs and dogs with various dermatologic disorders (atopic dogs, dogs with pyoderma, and atopic dogs with *Malassezia* dermatitis) (Pappalardo, Martino, and Noli, 2002), significant differences were noted among the groups in anal sac size, color, or consistency or in the presence of granules in the content. However, an unpleasant odor was found significantly more frequently in dogs with *Malassezia* infection and in those with atopy. Pasty secretions were noted most commonly and were brown or dark brown in color; whereas in viscous or liquid secretions all colors were noted and evenly distributed among cream, beige, brown, dark brown, and red-brown.

Cellular Characteristics

Cellularity in normal dogs was somewhat similar and showed keratinocytes (Robson, Burton, and Lorimer, 2003), and parabasal epithelial cells (Lake et al., 2004). Neutrophils were noted in both studies, although degenerate neutrophils were predominant in one study (Robson, Burton, and Lorimer, 2003) and nondegenerate cells were noted in the other (Lake et al., 2004). In another study (Pappalardo, Martino, and Noli, 2002) neutrophils were noted in 12.5% of normal dogs and 30% of dogs with *Malassezia* and atopic dermatitis, in 70% of dogs with pyoderma, and in 80% of dogs with uncomplicated atopic dermatitis. Erythrocytes and eosinophils were not noted with any regularity in any study.

Bacterial Characteristics

Bacterial counts were also detailed in these studies. In one report (Robson, Burton, and Lorimer, 2002) indicated that coccoid bacterial counts were low, with 77.9% containing few coccoid organisms and only 2.4% demonstrating more than 319 organisms per oil immersion field. This is in contrast to a study by Lake (2004) that reported that 86% of anal sac secretions contained mostly gram-positive cocci; Pappalardo, Martino, and Noli (2002) reported that 48.75% of all normal dogs had “abundant” numbers of bacteria present. However, all dogs with various skin diseases had higher numbers of bacterial counts,

ranging from 60% in atopic dermatitis without complications to 90% in dogs with pyoderma. Each of these studies did find that intracellular bacteria and large numbers of *Malassezia* organisms appear to be a relatively uncommon finding. Previous studies have revealed the presence of various gram-positive coccoid and rod-shaped bacteria as a normal part of the flora of the anal sac and include *Streptococcus faecalis*, *Streptococcus faecium*, *Escherichia coli*, *Clostridium perfringens*, *Staphylococcus intermedius*, *Proteus* spp., and coagulase-negative staphylococci. In the most recent study to evaluate cultures of the anal sac secretions, Pappalardo, Martino, and Noli (2002) found the most common organisms to be *Proteus mirabilis*, *E. coli*, *Streptococcus intermedius*, β -hemolytic *Streptococcus* spp., *S. faecalis*, *Bacillus* spp., and *Pseudomonas aeruginosa*.

Thus, although these recent studies seem to indicate variability in the physical characteristics of anal sac secretions, they do add significant data to this field in helping to allow the clinician to use visual and microscopic evaluations to establish the presence or absence of disease of the anal sac.

DISORDERS OF THE ANAL SAC

Impaction

Diseases of the anal sac vary from impactions, infections (sacculitis) with or without abscessation, and neoplasia. Anal sac impactions have been reported to occur in 2% to 12% of dogs (Scott, Miller, and Griffin, 2001). Clinically these usually result in pruritus or the classic “scooting” that is noted by most owners. Although anal sac disease is a common cause of anal pruritus, the clinician should be alert to the fact that many other causes of pruritus to the anal or perianal area have been documented and may include any number of dermatologic, psychologic, metabolic, nutritional, and gastrointestinal diseases. Skin diseases such as atopy, food allergy, insect hypersensitivity, *Malassezia* or bacterial dermatitis, parasitic skin disease, and keratinization defects may all result in persistent pruritus of the anal or perianal areas. Diagnostic procedures such as cutaneous cytologic evaluations, skin scrapings, dermatophyte cultures, food trials, and allergy testing may be necessary to uncover the causes of any residual pruritus. However, if the pruritus completely resolves after expression of the anal sac, a true anal sac disorder is likely. In addition, I strongly advocate that the routine expression of anal sacs in dogs during grooming, bathing, and boarding processes by veterinarians, technicians, groomers, and others be discouraged. Chronic manipulation and inadvertent trauma may predispose normal dogs to chronic recurrent anal sac disease.

Increased incidence of impactions has been associated with smaller breeds (under 15 kg), especially miniature and toy poodles, Chihuahuas, American cockers, and English springer spaniels (Scott, Miller, and Griffin, 2001). The presence of dermatologic problems such as primary or secondary keratinization defects in the spaniels may also be an accentuating factor. Impaction of the anal sacs in cats is less common. Secretions of the cat anal sac are somewhat different in that the anal sacs of cats contain larger amounts of sebaceous glands, which may allow for

more lipid production and subsequently easier expression. In addition, since the anal duct opens laterally to the anus in cats, it may be less susceptible to occlusion by fecal matter.

Impaction may be a result of alterations of glandular secretion. Loss of apocrine secretions may result in hard granular material that is unable to be expressed by the normal bowel movement of the dog. Glandular hypersecretions associated with generalized seborrhea may also cause plugging of the duct. Chronic loose stools or bouts of diarrhea may result in pasty secretions and subsequent impaction. Dietary manipulation with higher-fiber diets or endoscopic investigation for the possibility of gastrointestinal diseases causing chronic soft or loose stools may be of benefit. In addition, tapeworm segments have been identified in anal sacs and may cause impaction.

Impactions should be gently but thoroughly manually expressed. Complete expression of the anal sac is best accomplished via digital compression through the rectal canal. In addition, a complete palpation of the anal sac can be achieved. Expression should relieve the pruritus associated with a simple impaction. If pruritus is not resolved, additional causes of anal pruritus should be investigated as discussed previously. Sedation and irrigation of the anal sac with sterile saline may be required to soften firmer secretions or for more recurrent impactions. Every attempt should be made to elucidate and correct underlying causes for chronically recurrent impactions. If the pruritus is not relieved by manual expression, infection or inflammation of the anal sac may also be present.

Anal Sacculitis

Chronic or recurrent impactions may predispose to infection and abscesses of the anal sac. Prolonged retention may result in fermentation followed by inflammation and bacterial infection. Infection may stay confined to the anal sac or spread to surrounding subcutaneous tissues with resultant abscessation. Rupture of the anal sac may result in a cellulitis as well. Clinical signs of anal sac infections include pruritus, a hesitancy to sit or lift the tail, and pain that may be mild to severe with a swollen perineum in the cases of abscessation. Some animals may be unwilling to defecate, which may result in additional gastrointestinal concerns. When rupture of the perineum occurs, it is usually just lateral to the anus. Abscesses in cats must be differentiated clinically from cat bite abscesses, although, with the exception of the Siamese, infections of the anal sacs are rare in the cat (Scott, Miller, and Griffin, 2001). No studies have undertaken to quantify the physical characteristics of cat anal sacs. A greenish, and blood-tinged or purulent foul-smelling discharge with or without the presence of intracellular bacteria in the dog (and likely the cat) would be suspicious of infection.

Treatment options for infections vary with the severity. Routine expression with infusion of antibiotic-containing ointment may be curative in some cases; however, refractory or recurrent cases may need more aggressive therapy. Patients may need to be sedated or anesthetized, and the anal sacs infused via a tomcat catheter or lacrimal flush canula with ceruminolytic agents to break up thick secretion, followed by antibacterial lavage and ointment (otic

or ophthalmic preparations). This may need to be repeated weekly to biweekly initially to resolve the infection.

Abscessed anal sacs may need to be drained surgically with an incision and curettage. Healing may be by granulation. Broad-spectrum oral antibiotics that have efficacy against most gram-positive cocci such as cephalosporins, macrolide antibiotics (clindamycin), or amoxicillin-clavulanate should be considered. Treatment should continue until no evidence of typical infectious discharge or intracellular bacteria is noted, likely 2 to 3 weeks. Last, surgical excision or marsupialization may be necessary for any chronically impacted or infected anal sac. Surgical techniques for both procedures are described in most surgical texts and are considered routine. However, caution should be exercised by the clinician in recommending anal sac removal as a resolution for anal pruritus. I routinely see cases in which chronic anal sac disease is attributed to chronic pruritus of the perianal area; however, the problem persists even after removal of the anal sacs.

Neoplasia

Adenocarcinoma is by far the most common neoplasm affecting the anal sac (also see Chapter 83). However, other neoplasms have been noted recently, including squamous cell carcinoma arising from the lining of the sac (Esplin, Wilson, and Hullinger, 2003) and at least one case of malignant melanoma has been noted (Emms, 2005). Most previous reports note a female predisposition for adenocarcinomas; however, a more recent review of 113 cases found an approximately equal distribution between male and female dogs (Williams et al., 2003). This same study reported the clinical signs at initial presentation to consist of perianal swelling (61% of dogs), tenesmus (34%), perianal pruritus (30%), perianal bleeding (24%), polyuria/polydipsia (22%), and scooting (21%). In addition, no clinical signs may be noted in some cases, and the masses found on routine palpation. Although the presence of hypercalcemia was not present in all dogs, it was identified as a significant predictor in survival time in treated dogs; dogs that exhibited hypercalcemia survived 256 days, and normocalcemic dogs survived 584 days. Other factors that resulted in significantly shorter survival times included treatment with chemotherapy alone, no surgical intervention, and a tumor size larger than 10cm².

Perianal Fistula

Perianal fistula (or anal furunculosis) is a disease characterized by deep fistulous tracts and ulcerating sinuses that occurs in the perianal tissue (also see Chapter 122). German shepherds are predisposed, although the pathogenesis of the disease is not well understood and likely involves a number of genetic and immune mechanisms. The pathophysiology and relationship to the anal sac proper are also unclear. Clinical signs generally involve significant anal discomfort, pruritus, and tenesmus with variable amounts of purulent discharge noted to the tracts and fistulae. These lesions often begin with small tracts that ultimately coalesce to form large connecting

sinuses and ulcerative areas. These tracts may extend deep into the perianal tissues and involve the anal sacs themselves. Numerous therapies have been advocated over the years, and until recently surgical intervention to dissect the sinuses and remove anal sacs was the therapy most commonly used. However, a number of newer medical therapies have been used more recently with often better success and less risk of surgical complications.

In multiple studies cyclosporine, 5 mg/kg daily, has been shown to be quite effective at resolving fistulae and allowing for complete resolution of disease. Relapses do occur, however, and side effects (most notably vomiting and diarrhea) can be seen that limit the use of this drug in some dogs. Furthermore, the expense of cyclosporine can be a concern for clients. Recently a combination ketoconazole and low-dose cyclosporine has been advocated to reduce the dosage of the cyclosporine needed for remission and control of symptoms. In one study (Mouatt, 2002) 16 dogs were treated with 10 mg/kg of ketoconazole once daily in conjunction with cyclosporine at 1 mg/kg twice daily for 16 weeks. Complete resolution was noted to the perianal fistulae in 13 of 14 cases that completed the study. In addition, 7 of 14 of those had no recurrence after 12 months. The use of this combination therapy may create less concern for cyclosporine side effects and immune suppression and help to mitigate cost concerns in treating large dogs. Another therapeutic modality, tacrolimus ointment, which is a potent immunosuppressive medication, has also been evaluated in dogs with perianal fistulae. One published study (Misseghers, Binnington, and Mathews, 2000) evaluated 10 dogs with perianal fistulae that were treated with topical tacrolimus ointment once or twice daily for 16 weeks. Full resolutions of the fistulae were noted in 50% of the dogs, with noticeable improvement in 90%. I routinely use both therapies in conjunction when treating clinical cases of perianal fistulae. Topical therapy initially is often difficult in these dogs because of pain; therefore initial therapy with cyclosporine and ketoconazole or cyclosporine alone for the first 4 weeks aids in shrinking the lesions and minimizing

pain. Once this is achieved, topical tacrolimus 0.1% ointment applied twice daily should be initiated. Once the lesions are resolved, discontinuation of the oral therapy and continued use of the topical tacrolimus have resulted in excellent results in managing and maintaining these cases in clinical remission. Additional studies with tacrolimus may provide further support for this less invasive and less expensive therapy as an alternative approach to perianal fistulae.

CHAPTER 108

Acral Lick Dermatitis

JOHN M. MacDONALD, *Auburn, Alabama*
DINO M. BRADLEY, *Skillman, New Jersey*

Acral lick dermatitis (ALD) is a multifactorial condition characterized by excessive, compulsive licking at an area of the extremities resulting in a firm, proliferative, ulcerative, alopecic plaque or plaques. This condition, also referred to as *lick granuloma* and *acral*

pruritic nodule, remains one of the more challenging and frustrating problems seen by both the specialist and the private practicing veterinarian. One of the more difficult aspects of the treatment is related to the multifactorial etiology. Although environmental stress such as

boredom, confinement, loneliness, or separation anxiety may contribute to the onset of the condition, it appears to be less important than other factors.

By definition the lesion is located on an extremity, and cases appear to be distributed equally between the front and rear legs, most noticeably on the dorsal aspect of the carpus, metacarpus, tarsus, or metatarsus. Lesions usually begin with a small area of self-trauma and alopecia and progress to more extensive lesions through persistent licking or chewing. The expansion of the lesions often produces tissue proliferation and scarring and may interfere with locomotion. In some situations this can result in deeper bony tissue alterations. This condition is more commonly seen in older (5 to 12 years old), large-breed dogs (Doberman pinscher, Great Dane, Golden retriever, Labrador retriever, German shepherd, and boxer), although it has also been observed in other breeds, including the dalmatian, English setter, shar-pei, and weimaraner, and may afflict any breed of dog.

The development of ALD may be related to numerous causes. Constant licking of the affected area results in hair loss, erosions, or ulcerations. Exposure of the sensory nerve endings can cause or intensify the site to be pruritic, and the dog licks the affected area to alleviate the pruritic sensation. This perpetuates a vicious cycle, resulting in the development of an ulcerated skin lesion, which does not heal because of the dog's constant self-trauma. This condition should be approached as are other dermatologic problems in which a *primary disease* becomes complicated by *perpetuating factors* and results in persistence of the problem. Since there may be a number of simultaneous diseases and factors causing ALD, it is apparent that no single treatment is effective in treating all cases. Symptomatic therapy may decrease the compulsive tendency of licking but is unlikely to resolve the lesion, particularly in a dog with a chronic history. Although conventional treatments such as intralesional injection with glucocorticoids (triamcinolone or methylprednisolone acetate) may produce an antiinflammatory effect, they actually may intensify the infection that is almost always present. History taking becomes an important part of the diagnostic approach to these cases, and identifying an underlying disorder is truly the key to successful management.

PRIMARY FACTORS

Although boredom and stress factors are often considered predominant causes of ALD, they seem to be less important than other *primary* factors (Box 108-1). There is some variability with regard to certain breeds. The Great Dane and Doberman pinscher often do not have an obvious coexisting problem or underlying disease associated with the ALD. In contrast, in many other breeds allergy is the primary cause of the initial compulsive licking. Secondary bacterial folliculitis further potentiates and perpetuates the development of the lesion, especially in the Labrador retriever, Golden retriever, German shepherd, shar-pei, and dalmatian. Allergic diseases to be considered include canine atopy (see Section V on Evolve), food allergy, and flea allergy. Historical information about early-onset pruritic disease may be helpful

Box 108-1

Primary Causes and Perpetuating Factors in Acral Lick Dermatitis

Primary Factors	Perpetuating Factors
Allergic dermatitis	Bacterial infection
Arthropathies	Osteomyelitis
Foreign bodies	Keratin foreign bodies
Neuropathies	Periostitis
Trauma	Secondary arthritis
Neoplasia	Learned behavior
Mycotic infection	
Parasitism (e.g., scabies)	
Psychogenic factors	

in defining the relationship of allergy to the evolution of these lesions. Food allergy has notably been related to the development of ALD and may result from an abrupt onset of aggressive pruritus and occur spontaneously in the older dog (>6 years).

PERPETUATING FACTORS

Perpetuating factors may be as important as the primary cause and, if left untreated, ultimately result in failure to control the problem (see Box 108-1). One of the most important of these factors is infection. The infectious agent most commonly isolated from lesions of ALD is *Staphylococcus intermedius*. Infection starts as an area of folliculitis and progresses further to furunculosis. Histologic and microbial assessments of ALD lesions almost always demonstrate infected tissue. Treatment for bacterial infection should routinely be included in the therapeutic regimen. Although lesions are not exudative, cultures of aseptically acquired tissue almost always reveal a staphylococcal species and in chronic cases may include a gram-negative organism (*Pseudomonas*, *Proteus*, *Escherichia coli*).

It is well recognized that licking or scratching incites a cycle of irritation and intensifies pruritus. A theory of potentiation of this behavior suggests that endorphin release as a consequence of chronic licking induces repetition of the activity. Regardless of the mechanisms involved, the learned behavior of chronic licking may present an obstacle as a perpetuating factor that will impede resolution of the problem even if the primary and other perpetuating factors are no longer present. Thus most ALD cases involve both primary factors and consequential perpetuating factors. If the problem were as simple as a psychogenic or obsessive-compulsive behavioral disorder, treatment with psychoactive drugs should demonstrate greater efficacy than is currently observed.

DIAGNOSTIC APPROACH

One of the common causes of failure in the treatment of ALD is the inability to identify either primary or perpetuating factors. The appearance of the lesion nearly always elicits a "knee-jerk" response with regard to the name of the problem and an oversimplistic approach.

Associated and underlying factors are often overlooked. Routine topical or systemic therapy is instituted before understanding the relationships involved with the disease evolution and progression. Although ALD may be considered a purely psychogenic phenomenon, the diagnostic plan must include tests to rule out underlying causes of chronic licking and self-mutilation. Initial appraisal of focal or multifocal lesions should include documentation of location and size. Calipers may be used to quantify the size and shape of the lesion. The use of acetate film or plastic kitchen wrap and an indelible felt-tip pen provides a convenient method for tracing the lesion. A permanent record may be kept for comparison during the treatment process. Routine blood work (complete blood count and survey profile), urinalysis, and a minimal database of skin scrapings, impression or aspiration cytology, and a dermatophyte test medium culture should be obtained. Suspicion of possible underlying disease should influence the direction of diagnostics for that individual animal. History of allergic episodes should direct the clinician toward pursuing allergic disease.

Skin Biopsy

Biopsy of lesions associated with ALD remains controversial among some dermatologists, although it is included as part of our diagnostic workup. This provides a relatively expedient way to rule out neoplasia or mycotic infection with a similar cutaneous presentation. Mast cell tumor, histiocytoma, and squamous cell carcinoma are examples of tumors that may be associated with compulsive licking of the area. Likewise, infectious diseases, including superficial keratinophilic fungi (dermatophytosis), deep mycoses (blastomycosis), or sporotrichosis, may all be ruled out by this procedure. Histopathologic features usually are not diagnostic but show characteristic features that include an ulcerative lesion surrounded by irregular epidermal hyperplasia; mild perivascular inflammation of neutrophils, mononuclear cells, and plasma cells; and dermal fibroplasia. Epitrichial sweat glands are often surrounded by plasma cells, and sebaceous glands are hyperplastic. A specific type of a dermal fibroplasia has been described, with ALD referred to as “vertical streaking” when there is perpendicular fibroplasia seen in the papillary dermis. Tissue may also be sent for microbiologic evaluation (bacterial culture and susceptibility testing or fungal culture) during this procedure. Impression smears made from biopsy specimens should be obtained routinely, with the expectation of aiding in the diagnosis of neoplasia or infectious diseases.

Radiography

Depending on the chronicity and progression of the lesions, radiography may or may not be included in the initial diagnostic approach. This is certainly indicated with chronic and larger lesions or if there is concern about an underlying arthropathy associated with the problem. Radiography is most helpful when evaluating the prognosis. Lesions with more extensive radiographic evidence of bony involvement are least likely to be satisfactorily resolved.

Fine-Needle Aspiration and Cytologic Studies

Fine-needle aspiration should be included in the initial phase of the diagnostic workup to provide early recognition of cutaneous neoplasia, especially if biopsy specimens are not going to be acquired, although lack of evidence does not rule it out. Cytologic examination of material acquired from the typical ALD lesion shows little cellularity aside from representative inflammatory cells. Impression smears of the surface exudate contain many different bacteria and white blood cells, demonstrating opportunistic colonization of an ulcerative lesion.

Bacterial Culture and Susceptibility Testing

Bacterial cultures are often included in the diagnostic workup but must be obtained from an aseptically acquired biopsy punch specimen to offer credible results. Punch biopsy samples from the center of a lesion are submitted for maceration and inoculation to a microbiology laboratory on culture medium for identification of microorganisms. Transport media must be used if specimens cannot be taken to the laboratory promptly. Several commercial products that contain Stuart's transport media are available and are appropriate for this purpose. Culture may be helpful in chronic lesions, particularly when gram-negative organisms may be present. Culturing the *surface* of the lesion offers little diagnostic help in either antibiotic selection or understanding the relationship of perpetuating factors. Some clinicians use a Culturette to sample the defect left by a punch biopsy, but in our experience this method is not reliable in identifying important microorganisms.

Electrodiagnostic Testing

Electrodiagnostic testing consisting of electromyography and motor-sensory nerve conduction velocities may be conducted to rule out the presence of an underlying neuropathy or nerve root lesion. Results of these studies are not generally useful, except in situations in which automobile accidents or other types of trauma may result in peripheral neuropathy.

Allergy Testing

Allergy testing should be considered a part of the diagnostic evaluation if canine atopy is suspected based on history and clinical symptoms. Intradermal allergy testing or in vitro allergy testing is desirable for identification of allergens with the anticipation of implementing antigen therapy (Bonagura, 2000, p. 560). Although this does not have an immediate effect on the active lesion, it may be helpful in preventing further lesions. Intradermal allergy testing may need to be deferred if repeated intraleisional injection of glucocorticoids has been performed. Of course, treating the primary problem may not provide a measurable contribution if the perpetuating factors represent a large component. Food trials should be considered routinely in animals in which food allergy is suspected, particularly the Golden retriever, Labrador retriever, shar-pei, dalmatian, and German shepherd.

TREATMENT

There is no *one* specific treatment for ALD. Identifying and specifically treating the primary condition and the perpetuating factors are critical to satisfactory resolution. Chronic unresponsive lesions have an extremely poor prognosis for resolution. Preventing licking by introduction of mechanical barriers should be included in the initial phase of all therapy. Bandaging may have limited value because of rapid removal by the dog, but it may be helpful in certain cases. Wire muzzles and bandaging have proved a good combination for deterring continued licking. Elizabethan collars, although poorly accepted by most pet owners and their pets, can be effective. An alternative to the Elizabethan collar is the use of a plastic bucket with a hole cut in the bottom. This can be slipped over the head and secured to a collar. Some innovative pet owners and veterinarians have used modified polyvinyl chloride piping to cover lesions and provide sufficient air flow through perforations so as not to cause dermatitis. Intermittent examinations are critical to determine response to therapy. We strongly recommend the use of a measuring mechanism and digital pictures to record changes in the size of focal lesions so that their progression can be followed.

Antibiotics

Antibiotics are one of the most important treatments of ALD. These agents should be used systemically, and therapy may require a protracted period (4 to 6 months). The selection of antibiotics should be based on culture and susceptibility testing when available. Cephalosporins have been used commonly with more success than other antibiotics (e.g., cephalexin [Keflex, Lilly and generics] 30 mg/kg orally [PO] q12h; or sulfadimethoxine/ormetoprim [Primor, Pfizer] 55 mg/kg for the first day and then 27 mg/kg once daily thereafter). Fluoroquinolones, including enrofloxacin (Baytril, Bayer) 5 mg/kg once daily or marbofloxacin (Zeniquin, Pfizer) 2.5 mg/kg once daily, have been useful, particularly if there is significant scarring or if gram-negative organisms are present. Treatment of the animal should be carried out 3 to 4 weeks beyond regression of the lesion. Maintenance antibiotic therapy may be required in the event of incomplete resolution of the lesion or when the lesion recurs after the termination of antibiotic administration. Pulse therapy has been used successfully in some cases in which administration of antibiotics is alternated with periods of no antibiotics.

Treatment of Allergic Diseases

Allergen-specific immunotherapy (see Chapter 92) should always be considered when canine atopy has been determined to be one of the primary factors. The decreased use of systemic glucocorticoids is an objective of treatment in chronically infected lesions, and antigen therapy may help accomplish this goal. It is important with any allergic condition to consider avoidance as an optimal treatment, but practically this is limited to food or flea allergy. ALD predominantly affecting the rear legs with coexisting lesions over the pelvic area should be evaluated for

flea allergy and treated with parasitocidal therapy regardless of gross observation of fleas. The products most helpful for this trial include “on-the-animal” adulticides such as imidacloprid and fipronil. Dietary trials and challenge should be used to identify the optimal food for routine feeding of the food-allergic or food-intolerant animal. Owners should be cautioned about deviating from the restricted food.

Cyclosporine (Atopica, Novartis) has also proved to be of substantial value in controlling ALD associated with allergic skin disease. Following protocols used for management of atopic dermatitis can be quite helpful (see Chapter 84).

Systemic Glucocorticoid Therapy

Although systemic glucocorticoid therapy is contraindicated in many cases of ALD because of the concurrent presence of bacterial infection, its judicious use after infection is addressed can be helpful in many cases. It can often break the licking and chewing cycle to allow healing to occur. It can reduce pain and inflammation and aid in the reduction of scar tissue formation. If used, oral formulations of prednisone, prednisolone, or methylprednisolone are first-choice selections at routine antiinflammatory dosages. In some situations the use of oral triamcinolone is selected since it may have more dramatic effects on reducing scar tissue formation than other glucocorticoids. The use of glucocorticoids should be short term, and tapering to the lowest effective alternative dosing is recommended within 2 weeks of initiation (see Chapter 89).

Surgery or Cryotherapy

Surgical intervention is often met with postoperative complications and incomplete resolution of the problem. This is a salvage procedure and indicated if underlying arthropathy is identified in a location where arthrodesis may be used for joint stability and pain reduction. Foreign bodies are also treated surgically. Surgical excision of the lesion does not prevent recurrence. The primary disease must be treated.

OTHER THERAPY

Some clinicians have reported laser therapy to be beneficial. Other reports suggest that this treatment can be partially helpful, depending on the underlying cause, but should be used cautiously. In a small number of cases acupuncture has been reported to be beneficial.

Radiation Therapy

Radiation therapy has been used for treatment of ALD with varying degrees of success. The earlier, less-pronounced lesions with minimal fibrosis and inflammation demonstrate the best response; whereas larger, chronic lesions with underlying bony involvement do not respond as well. The cost factors and unavailability of treatment centers make radiation therapy impractical in the vast majority of cases unless the underlying lesion is a radiosensitive tumor with a difficult surgical approach.

Topical Antipruritic and Antiinflammatory Treatment

The sole use of topical antiinflammatory drugs has a limited effect in the majority of cases in our experience. They may be prescribed after initial resolution has been observed with antibiotic therapy. A variety of choices are available, including Tresaderm (Merck Ag Vet), Otomax or Momentamax (Schering Plough Animal Health), or the Synotic-Banamine combination. Synotic-Banamine is preferred, and preparation is made by placing 3 ml of flunixin meglumine (Banamine, Schering Plough) in a vial of Synotic (Syntex) with application twice daily for 30 days. The use of capsaicin (Zostrix, GenDerm) has been helpful in some cases. This compound is a substance P inhibitor that is available as an antiarthralgic-myalgic preparation in ointment form for human application. The topical application on and around lesions may help decrease the reinforcing sensations but must be used consistently at a rate of three to four times per day. This drug is now available as a nonprescription item. It is formulated as a 0.025% and 0.075% ointment. A more concentrated formulation (Dolorac, GenDerm) contains 0.25% capsaicin. We have used this in combination with mupirocin antibiotic (compounded generics) in a 1:1 mixture applied three times daily. The use of bitter apple and Heet Liniment (Whitehall) in a ratio of two parts bitter apple to 1 part Heet has also been popular as a topical antipruritic therapy. Heet contains capsaicin (0.025%), methylsalicylate (15%), and camphor (3.6%) and has activity similar to that of the generic capsaicin or Zostrix. A substantial trial period is necessary (4 to 6 weeks) to evaluate these topical products. It must be stressed that this type of treatment by itself has little impact on chronic lesions. Specific treatments of the primary and perpetuating factors are critical for any hope of resolving the lesions.

Intralesional Injection

Intralesional injections of glucocorticoids are *not* recommended, particularly in the early stage of disease management, because the vast majority of lesions are infected with *Staphylococcus* spp. and possibly by gram-negative microorganisms. Many acute lesions become chronic in nature with progression of the infection. Acute lesions should be treated with a regimen of antibiotic therapy before consideration of intralesional steroid therapy. Topical antiinflammatory drugs are far more conservative and would be better used in lieu of intralesional steroid therapy. We have seen cases that require protracted treatment with antibiotics (>13 months) when the lesion had been treated with glucocorticoid therapy. Intralesional steroid injections should be withheld at least until a complete appraisal of the case has been made and a course of antibiotic therapy evaluated.

CANINE ACRAL LICK DERMATITIS AND OBSESSIVE-COMPULSIVE DISORDER

There may be similarities between the uncontrollable licking experienced by dogs suffering from ALD

and the uncontrollable actions of humans suffering from obsessive-compulsive disorder (OCD). This condition in humans is characterized by recurrent, persistent thoughts or impulses (obsessions) or by repetitive, unnecessary behavior (compulsions). OCD, expressed by acts such as chronic hair pulling (trichotillomania), hand washing, or nail biting, has been considered an exaggeration of normal grooming habits. Some think that ALD is a manifestation of exaggerated grooming habits in animals.

Investigations into the etiology of OCD indicate that these patients have an abnormality in the pathway that links the frontal lobes of the cerebral cortex with the basal ganglia. The frontal lobes promote deliberation and judgment, with the basal ganglia serving as a relay station for planning and execution of movements. It is suspected that the caudate nucleus, a portion of the basal ganglia, is deficient in filtering messages from the frontal lobes to the rest of the brain.

Biochemically it appears that serotonin is linked directly with the presence of OCD. Simply stated, serotonin is a neuromodulator that plays a role in sensory perception, emotion, arousal, and higher cognitive functions. Serotonin-releasing fibers are distributed throughout the central nervous system, influencing the sleep cycle, sex drive, body temperature, appetite, respiration, cardiovascular activity, mood, and aggression.

After a meal serotonin (5-hydroxytryptamine [5-HT]) is made from the amino acid L-tryptophan after it reaches serotonin-releasing neurons in the brain. Once synthesized, serotonin is enclosed within vesicles at the presynaptic terminal. An action potential at the presynaptic terminal releases the serotonin into the synaptic gap, allowing binding to specialized receptors on the postsynaptic neuron. The serotonin is removed from its binding site and transported back to the presynaptic terminal, where it is reused or degraded to its primary metabolite, 5-hydroxyindoleacetic acid.

Experimentally it has been shown that the primary function of the brain serotonin system is to facilitate tonic motor actions and inhibit sensory information processing. In patients with OCD serotonin neuronal activity is low, resulting in impairment of these functions. It is thought that the repetitive motor activities of an OCD patient serve to increase serotonin neuronal activity. These repetitive acts are a means of self-medication. Since the pattern of exaggerated grooming behavior applies to canines, it would appear that the chronic licking of ALD may serve to increase serotonin neuronal activity as well.

Therapy Using Drugs That Modify Neurologic Activity

Recent clinical investigations indicate that certain medications effective in the treatment of OCD in humans have a similarly positive effect on dogs with ALD. The drugs that show the most promise are tricyclic antidepressants (TCAs) and selective serotonin reuptake inhibitors (SSRIs), which affect central serotonin neurotransmission. The specific mechanism of action is based on the

prevention of removal of serotonin from the synaptic cleft, increasing the functional activity of the serotonin. TCAs block the reuptake of both norepinephrine and 5-HT by their presynaptic terminals. Adverse reactions in humans include cardiotoxicity, resulting in arrhythmias or heart block, or central nervous system toxicity. SSRIs are more specific in their mode of action, acting to block reuptake of 5-HT by presynaptic terminals. This eliminates many of the adverse effects noted with the use of TCAs.

Clomipramine (Anafranil, Ciba-Geigy), a TCA, administered orally at a dosage of 1 to 3 mg/kg once daily, has shown some efficacy in the treatment of ALD in some dogs (Bonagura, 2000, p. 90). Because of the transient side effects of vomiting or diarrhea, we recommend treating the dog with 1 mg/kg orally for the first 3 days of therapy, with a gradual increase in dosage based on clinical response. The SSRI, fluoxetine hydrochloride, (Reconcile, Eli Lilly and Co.), administered at a dosage of 1 mg/kg orally once daily, has also been an effective treatment for ALD. Other SSRIs currently available for treatment of OCD in humans are paroxetine HCl (Paxil, SmithKline Beecham Pharmaceuticals) and fluvoxamine maleate (Luvox, Solvay Pharmaceuticals). Hydrocodone has been used in the treatment of ALD. The dosage is variable, pending response and tolerance of the drug. The standard dosage is 5 mg/20 kg of body weight twice daily and has also been used at 10 mg/20 kg of body weight three times daily.

These drugs should also be efficacious in the management of ALD in dogs, but there are no publications evaluating their clinical application for this particular condition. In any event, one should anticipate a lag phase of at least 4 to 5 weeks before any change in excessive grooming behavior is seen.

LINDA J. DeBOWES, *Seattle, Washington*

The most common cause of oral inflammation in cats is periodontal disease (gingivitis, periodontitis). Inflammation of the buccal mucosa (stomatitis) may also be associated with severe periodontal disease. Eosinophilic complex-related disorders, neoplasia, trauma, irritation caused by ingestion of noxious materials, immune-mediated diseases, and metabolic abnormalities are also potential causes of oral inflammation.

Infectious diseases have been related to oral inflammation. Cats with altered immune function from infection with feline leukemia virus or feline immunodeficiency virus may have more severe periodontal disease or oral inflammation. Chronic calicivirus infection has been implicated as a factor in severe oral inflammation, especially in cats with inflammation lateral to the palatoglossal fold (caudal stomatitis). In one study of 25 cats with gingivostomatitis, 81% were shedding both feline calicivirus and feline herpesvirus 1 compared to 21% in a similar number of cats with periodontal disease (Lommer and Verstraete, 2003). *Bartonella henselae* infection has been suggested as a possible factor in the development of feline chronic gingivostomatitis (Hardy, Zuckerman, and Corbishley, 2002). However, there is a high prevalence rate of *B. henselae* antibody-positive healthy cats, making it difficult to determine the significance of an antibody-positive test in a cat with chronic gingivostomatitis. A recent study of 34 cats with chronic stomatitis and 34 age-matched healthy control cats reported no significant differences in the prevalence rates of polymerase chain reaction-positive (*Bartonella* spp.) cats and antibody-positive (*B. henselae*) cats between the two groups (Dowers and Lappin, 2005).

Cats with chronic gingivostomatitis have decreased salivary IgA compared to healthy cats; however, the significance of this in the development of disease is unknown (Harley, Gruffydd-Jones, and Day, 2003). Cats with chronic gingivostomatitis also have higher serum immunoglobulin (Ig)G, IgM, and IgA concentrations compared to healthy cats.

Oral inflammatory disease of unknown cause is a common problem in cats. The degree of inflammation is variable and may be severe. These cats present a diagnostic and therapeutic challenge, and management is frequently frustrating for both the veterinarian and owner. Inflammation may involve the gingiva (gingivitis), buccal mucosa (stomatitis), or tissues of and adjacent to the palatoglossal fold (caudal stomatitis) or pharyngeal area (pharyngitis). Current knowledge about the cause of chronic gingivostomatitis unrelated to periodontal disease in cats is limited. The condition has been referred to as lymphocytic-plasmacytic stomatitis based on the major cellular infiltrate present on histologic examination.

The histologic description is compatible with a chronic inflammatory or immunologic response but does not provide a definitive diagnosis as to the primary cause. Cats with severe chronic gingivostomatitis are often grouped together as all having the same unknown problem; yet, based on clinical presentation and variable response to treatment, it is more likely that multiple factors are involved.

HISTORICAL AND CLINICAL SIGNS

Cats with chronic gingivostomatitis frequently present with a history of dysphagia, inappetence, or anorexia and pain when eating is attempted. The cat may appear interested in food but is unwilling to eat or may attempt to eat but drops the food from its mouth or paws at its muzzle. The affected cat is usually reluctant to eat hard food but may eat soft food. As the severity of the inflammation increases, the cat becomes pickier about what it will eat, or blood-tinged saliva may be noted after eating. In severe cases the cat may be in a great deal of pain, causing a reluctance to swallow and drooling (pseudoptialism). Weight loss may be a significant problem, depending on the severity and duration of inflammation. Affected cats may exhibit altered behavior such as reduced activity, demonstrating aggressive behavior toward other pets or persons, or expressing an aversion to having their face or head touched. These cats may present with an unkempt appearance resulting from a reluctance to groom because of oral pain. Owners may notice that the cat no longer yawns.

ORAL EXAMINATION

Before examining the oral cavity, the regional lymph nodes should be palpated, and the mandible and maxilla examined for swelling or pain. It may not be possible to complete the initial oral examination if the cat has severe oral pain. In severe cases the inflamed tissues may be ulcerated and bleed readily. Proliferation of oral tissues may make it difficult to visualize the teeth. Cats with severe gingivostomatitis may have extreme pain on opening the mouth; thus the initial examination should be performed with the mouth closed while gently retracting the lips. This examination is performed slowly to minimize pain. The mouth is then opened gently if possible. Lesions of the oral cavity may include inflammation of the gingiva (gingivitis), oral buccal mucosa (stomatitis), and tissues lateral to the palatoglossal fold (caudal stomatitis). Often a complete oral examination is not possible without benefit of sedation or general anesthesia.

DIAGNOSTIC EVALUATION

A complete blood count, biochemical profile, and urinalysis are performed to identify concurrent or contributory diseases. The complete blood count is usually unremarkable. Hyperglobulinemia has been identified in some cats with chronic gingivostomatitis. Serologic evaluation for feline leukemia virus antigen and feline immunodeficiency virus antibody should be performed. It is ideal to include virus isolation studies on specimens obtained from oral swabs of inflamed tissues in cats with gingivostomatitis. Although bacterial cultures are not part of a basic evaluation in most cases, bacterial culture and sensitivity testing may be helpful in chronic cases that do not respond to the antibiotics commonly used for oral infections. A biopsy specimen of any lesion that appears neoplastic or of unknown cause should be obtained and submitted for histopathologic examination.

A complete oral and dental examination is performed with the cat under general anesthesia. The animal is evaluated for periodontal disease, tooth resorption, and other problems that may cause oral inflammation. Dental radiographs are obtained to evaluate for alveolar bone loss (indicating periodontitis), tooth resorption, and to identify retained roots.

MANAGEMENT

The goals of management are aimed at controlling plaque bacteria and decreasing the inflammatory and immunologic response. Controlling the plaque bacteria can be attempted by several methods, including scaling, topical antimicrobial application, systemic antimicrobial therapy, and tooth removal.

Cats that have generalized chronic gingivostomatitis, including caudal stomatitis, are best treated with extraction of all premolars and molars. This includes the extraction of any retained roots. Extraction of the teeth removes the surfaces that are available for plaque retention and consequently decreases plaque and the associated inflammation. Extractions are successful in decreasing inflammation when the plaque is initiating the excessive inflammatory response. Retained roots may be a source of residual bacteria and, if found in association with oral inflammation, should be extracted as well.

When an owner is not willing or able to proceed with extractions of premolars and molars, the cats should be managed with plaque removal, plaque control, and medications to suppress the inflammatory response. The first step is a complete scaling and polishing along with extraction of teeth that show evidence of periodontitis or tooth resorption. Oral antibiotic administration for 4 to 6 weeks following the dental surgery is recommended. In severe cases, when the patient is not eating, it is necessary to decrease the inflammation quickly so the patient will resume eating. To manage the inflammation and maintain appetite initially, most cats require methylprednisolone administration every 4 to 6 weeks and over time possibly as frequently as every 3 weeks. Alternatively other antiinflammatory or immunosuppressive drugs can be considered. Once the inflammation has decreased and the cat is eating, toothbrushing is instituted if the owners

are able to adequately brush the teeth and the cat is cooperative. Many owners are not able to brush the teeth sufficiently to decrease plaque accumulation and prevent inflammation. A topical rinse, using a 0.12% chlorhexidine product, is an adjunctive treatment in managing plaque accumulation. I inform the owners on the initial visit that extractions of all premolars and molars provides the best long-term results. Medical management with antibiotics and glucocorticoids generally loses effectiveness over time, and severe clinical signs return, requiring more aggressive medical management or extractions. For these reasons, the author believes that extraction of all premolars and molars provides the best long-term management for the majority of affected cats.

Extractions

Extractions are indicated when there is severe periodontitis or when teeth have type 1 tooth resorption. In addition to extractions for treatment of related periodontal disease and tooth resorption, removing healthy teeth is an option for cats with chronic gingivostomatitis. Plaque bacteria attach to the tooth surfaces (crowns and roots), eliciting an inflammatory response. Oral hygiene directed at plaque control is difficult in cats with severe inflammation and oral pain. Extraction of the premolars and molars removes the surfaces to which plaque attaches and therefore decreases the plaque in the cat's mouth. Dental radiographs are needed to confirm removal of all premolar and molar roots in these cats.

When inflammation is present adjacent to the incisors, they should also be extracted. It is rarely necessary to extract the canine teeth unless they have severe periodontitis or resorptive lesions. The response to extractions is variable, ranging from complete resolution of the inflammation to no improvement, and clients should be so advised. Cats tolerate extractions, even full-mouth extractions, very well and can eat dry and moist cat food without teeth. After extractions some cats may show significant improvement, and medical management may not be required to keep the cat free of clinical signs. Other cats may exhibit a partial response, requiring less aggressive medical management than that required before extractions. Another group of cats appears to have minimal response to extractions, and medical management is continued as before the extractions. In my practice cats that responded poorly to full-mouth extractions often were those in which calicivirus was isolated from the oral cavity or cats that received long-term (months to years) medical management. In a report of 30 cats with gingivitis, stomatitis, and faucitis (caudal stomatitis), the response to periodontal treatment and extraction of selected teeth, including retained root tips, was generally favorable (Hennet, 1994). Oral inflammation resolved completely in 60% (18 of 30) of the cats, with an additional 20% (6 of 30) responding with minimal residual inflammation and no oral pain. None of these 24 cats required medical treatment to manage oral inflammation after the treatment. Initial improvement requiring continued medical therapy to control clinical signs was found in 13% (4 of 30), and no improvement occurred in 7% (2 of 30) of the cats.

When long-term medical management becomes ineffective, or when side effects of drug therapy are unacceptable, extractions of the premolars and molars offer the next option. The maximal clinical improvement may require several weeks in cats with severe and chronic inflammation. Some of these cats may benefit from enteral feeding to maintain an adequate caloric intake (Chapter 3) and balanced nutrition.

Appropriate pain management should also be administered (Chapter 2). Buprenorphine HCL at 0.01 mg/kg to 0.03 mg/kg administered in the cheek (buccal mucosal absorption) every 6 to 12 hours for 3 days is usually adequate for postoperative pain control. Buprenorphine may also be beneficial for pain control in cats with owners who have chosen medical management.

Scaling and Polishing

The teeth should be scaled to remove plaque, bacteria, and calculus. Plaque bacteria may be a factor in the excessive inflammatory response present in these cats. The teeth should be polished after any scaling to smooth the tooth surface. Plaque attaches and becomes established on the tooth surfaces within several hours after the scaling and polishing procedures; therefore continued control measures should be undertaken. Cats with severe oral inflammation are usually in too much pain for toothbrushing to be practical; thus plaque control must be maintained initially with topical or systemic antimicrobial therapy. Once the oral inflammation is well controlled, the owner may attempt plaque control with toothbrushing. A finger toothbrush or small toothbrush designed for cats is used with an acceptably flavored veterinary dentifrice.

Antimicrobial Therapy

Antimicrobial therapy is best accomplished with systemic antibiotic administration. A variable response is observed with antibiotic therapy, although therapy of 4 to 6 weeks may result in improvement of clinical signs in some cats. Antibiotics as a single treatment are rarely effective in the initial management of inflammation, and combined treatment with antibiotics and glucocorticoids is usually required. Amoxicillin-clavulanate acid (Clavamox, Pfizer), clindamycin (Antirobe, Pfizer), and metronidazole are useful antibiotics in managing these cats. Repeated treatment with antibiotics may be necessary. Complete resolution of clinical signs is unlikely, and relapses are common. Topical chlorhexidine may be used for adjunctive antimicrobial therapy.

Antiinflammatory and Immunosuppressive Therapy

Immunosuppressive doses of glucocorticoids are required in most cats to decrease the inflammation and reduce pain sufficiently so the cat will eat. Methylprednisolone

acetate (Depo-Medrol, Pfizer) at 15 to 20 mg total dosage intramuscularly, subcutaneously is generally adequate, and cats usually demonstrate a decrease in the oral inflammation and a willingness to eat within 1 to 2 days. Satisfactory results are less common with oral prednisone administration in cats having severe inflammation. For cats demonstrating moderate improvement after extractions and requiring further control of residual inflammation, oral prednisone (1 to 2 mg/kg every other day) may be sufficient; however, higher doses may be required, with the ultimate dose being determined by the response. Clients should be cautioned about potential adverse effects of corticosteroids in cats, including diabetes mellitus and precipitation of congestive heart failure in cats with cardiomyopathy. Alternative immunosuppressive therapies such as gold salts or cyclosporine A (Chapter 55) have also been recommended as treatments, although I have limited experience with these drugs and little information currently available documenting the therapeutic effects of these drugs in affected cats.

Metacam (Merial) is an antiinflammatory that may provide an alternative for short-term control of inflammation before an extraction procedure. Long-term use of Metacam in cats with normal renal function to reduce clinically significant inflammation has had little success in my practice.

Miscellaneous Treatments

A trial treatment of coenzyme Q₁₀ (CoQ₁₀) supplementation at 30 to 100 mg daily for 4 months is recommended in cats with residual inflammation following extractions or as a supplement to medical management. There is anecdotal evidence of improvement in cats with chronic gingivostomatitis and humans with chronic periodontitis after 3 to 4 months of supplementation with CoQ₁₀. Prospective studies are needed to prove efficacy.

Oropharyngeal Dysphagia

G. DIANE SHELTON, *La Jolla, California*

Dysphagia, defined as an abnormality in swallowing, can be one of the most difficult diagnostic challenges encountered in clinical veterinary practice. Normal swallowing is a well-coordinated process involving the tongue, hard and soft palate, pharyngeal muscles, esophagus, and gastroesophageal junction. In addition to normally functioning striated muscle and neuromuscular transmission, the integrity of several cranial nerves, including sensory and motor fibers of the trigeminal nerve and facial nerves; the glossopharyngeal, vagus, and hypoglossal nerves; their nuclei in the brainstem; and the swallowing center in the brain reticular formation; are critical to the swallowing process. Difficulties in swallowing may be found in very young animals associated with congenital abnormalities or as an acquired condition in mature animals. Swallowing is a complex process, and abnormalities of this process have been classified functionally based on cineradiographic analysis as the oropharyngeal, esophageal, and gastroesophageal dysphagias (Suter and Watrous, 1980; Watrous and Suter, 1983). Because of the complexity, the diagnosis of swallowing disorders should be approached in a systematic manner. Esophageal and gastroesophageal dysphagias are described in Chapter 111.

As a clinical sign of oropharyngeal dysfunction, dysphagia is relatively common in dogs and less common in cats and can result from either morphologic or functional abnormalities. Structural changes that interfere with swallowing may include traumatic injury, strictures, foreign bodies, or neoplastic processes. Most functional abnormalities are caused by neurologic, peripheral nerve, neuromuscular junction, or primary muscle diseases. Dysphagia may be the sole presenting clinical sign or associated with multiple clinical abnormalities. A common misconception is that dysphagia is a specific disease. The term *cricopharyngeal achalasia* refers to a rare form of

dysphagia characterized by inadequate relaxation of the cricopharyngeal muscle occurring in very young animals and surgically treated with a myotomy. Dysphagia may also be part of a generalized inherited myopathy in young dogs such as a muscular dystrophy. It is most commonly an acquired condition in adult dogs with weakness of the pharyngeal muscles, resulting in inadequate propulsion of the bolus from the mouth into the proximal esophagus. In this context dysphagia is a clinical sign of disease and not a specific disease.

FUNCTIONAL ANATOMY

Oropharyngeal dysphagia can be divided into three stages based on the site of dysfunction: the oral, pharyngeal, and cricopharyngeal stages. The oral stage is characterized by bolus accumulation at the base of the tongue. In oral dysphagia there is difficulty in prehending and transporting food to the oropharynx. Rostral-to-caudal pharyngeal constrictors act in concert with the plungerlike action of the tongue to propel the bolus from the base of the tongue to the cricopharyngeal passage in the second or pharyngeal stage. The inability to propel a bolus from the base of the tongue to the cricopharyngeal region is characteristic of pharyngeal dysphagia. The cricopharyngeal or third stage consists of relaxation of the cricopharyngeal muscles (also referred to as the upper esophageal sphincter) and passage of the bolus into the cranial esophagus. Synchrony between constriction of the pharyngeal muscles and relaxation of the cricopharyngeal muscle allows the passage of a bolus into the esophagus. Failure of a normally propelled bolus to pass through the cricopharyngeal region is termed *cricopharyngeal dysphagia*. Clinical signs of the three stages of oropharyngeal dysphagia are described in Table 110-1.

Table 110-1

Clinical Signs Associated With Dysfunction in the Three Stages of Oropharyngeal Dysphagia

Clinical Sign	Oral Stage	Pharyngeal Stage	Cricopharyngeal Stage
Respiratory involvement	No	Yes	Yes
Differential ability to handle liquids and solids	No	Yes	Yes
Reduced gag reflex	Yes	Yes	No
Excessive salivation and drooling	Yes	Yes	Yes
Difficulty prehending food	Yes	No	No
Repeated attempts to swallow	No	Yes	Yes
Excessive head movement	No	Yes	Yes
Dropping food from the mouth	Yes	Yes	Yes

PHYSICAL AND NEUROLOGIC EXAMINATION

An accurate identification of a swallowing disorder is critical to reaching a specific diagnosis and devising a therapeutic plan. Visual examination of the oropharynx under tranquilization or general anesthesia may allow the identification of many of the morphologic abnormalities that cause oral dysphagia, including oral foreign bodies, dental disease, and neoplasia. Evaluation of cranial nerves should be performed, including assessment of tongue and jaw tone and abduction of the arytenoid cartilages with inspiration. Complete physical and neurologic examinations may identify clinical signs of a generalized neuromuscular disorder, including muscle atrophy, stiffness, or depressed or absent spinal reflexes (Glass and Kent, 2000).

Observation of the animal eating and drinking may demonstrate repeated unsuccessful attempts to swallow, excessive head movements, dropping food from the mouth, reingestion of dropped food, and gagging. The gag reflex should be evaluated by placing a finger in the pharynx. The normal response is to repel the finger from the pharyngeal area. An animal with a depressed reflex or absent sensory response may move its head away without actively pushing away the stimulus. Clinical signs of aspiration pneumonia, a common complication, and of esophageal dilation and regurgitation may occur concurrently with pharyngeal dysphagia. The cervical region should be observed for a ballooning esophagus.

DIAGNOSTIC TESTING

Neuromuscular Minimum Database

Once dysphagia has been identified on physical and neurologic examination, whether as the only clinical sign or associated with signs of generalized neuromuscular disease, the following minimum database is suggested: a complete blood count, serum chemistries, including creatine kinase (CK) activity and electrolyte concentrations, urinalysis, evaluation of thyroid function, and the acetylcholine receptor (AChR) antibody titer for acquired myasthenia gravis (MG). A persistently elevated CK, even if only mildly elevated, could be an indication of an underlying inflammatory myopathy. Markedly elevated CK activity may suggest a necrotizing or dystrophic myopathy. Electrolyte abnormalities may be indicative of an endocrine disorder such as Addison's disease. Neuromuscular complications of hypothyroidism have also been described.

Acquired MG is the most commonly diagnosed neuromuscular disorder in my laboratory and should be high on the list of differential diagnoses in dogs with a recent onset of dysphagia, whether alone or as part of a generalized neuromuscular disorder (Shelton, 2002). In a study of a large group of dogs with acquired MG (Shelton, Schule, and Kass, 1997), focal signs, including pharyngeal, esophageal, and laryngeal weakness without clinically detectable limb muscle weakness, were described in 43% of dogs. Pharyngeal weakness, as the

only clinical sign of MG, was described in 1% of the myasthenic dogs. Similarly focal signs, including megaesophagus and dysphagia, were described in 14% of cats in a similar study (Shelton, Ho, and Kass, 2000).

Imaging Modalities

Lateral survey radiographs of the neck are necessary to exclude radiodense foreign bodies or space-occupying lesions as causes of dysphagia. Thoracic radiographs may also demonstrate megaesophagus, a cranial mediastinal mass, or metastatic lung disease. Since swallowing is not a static process, motility should be evaluated fluoroscopically using both liquids and solids. All three phases of swallowing can be evaluated; the three stages of the oropharyngeal phase can also be separately evaluated.

Most recently magnetic resonance imaging (MRI) has been used to identify inflammatory lesions in difficult-to-diagnose cases of dysphagia (Fig. 110-1, Platt et al, 2006). In inflammatory myopathies, cellular infiltrates can have a patchy or multifocal distribution and be missed on individual biopsy specimens. The MRI examination can aid in locating lesions and guiding a diagnostic biopsy, or it can be used for follow-up examinations. Neoplasia involving cranial nerves may also be evident on MRI evaluations. Areas of hyperintensity may also be identified on screening examinations when the diagnosis is in question. Since dysphagia may be the primary clinical abnormality in dogs with inflammatory myopathies (Ryckman et al., 2005) without other clinically evident signs of generalized weakness, imaging studies should be performed as an early diagnostic procedure.

If a central cause of pharyngeal dysphagia is suspected based on the clinical signs and neurologic examination, evaluation of the brain by MRI should be performed along with concurrent evaluation of the cerebrospinal fluid. Evaluation of intracranial diseases is described in standard textbooks of veterinary neurology.

Electrodiagnostic Testing

Electrodiagnostic evaluation, including electromyography and measurement of motor and sensory nerve conduction velocities, can provide important information as to the severity, distribution, and character of a myopathic or neuropathic disease process. In addition to evaluation of limb muscles, testing should also include evaluation of the pharyngeal muscles and tongue. Results of these studies can help guide the direction of biopsy procedures. Electrodiagnostics are performed by specialists trained in the procedures, are generally available only at referral centers, and must be performed under general anesthesia. Since a lengthy anesthesia is required for these procedures, the health status of the animal must be taken into consideration, weighing the risks and benefits. In cases of suspected MG, evaluation of the serum AChR antibody titer should be performed before anesthesia. If the antibody titer is negative and a diagnosis of MG is still a consideration, electrodiagnostic testing can then be performed to measure the

Fig. 110-1 **A**, Transverse T1-weighted image of the laryngeal and pharyngeal muscles in a 2.5-year-old female Briard with dysphagia. There is a mild isointense to hyperintense signal present compared to normal muscle. (TR, 500 ms; TE, 10 ms; arrow head is pharyngeal muscle, arrow is laryngeal muscle). **B**, Transverse T1-weighted image of the laryngeal and pharyngeal muscles post-contrast administration demonstrating a hyperintense signal in the associated musculature. (TR, 500 ms; TE, 10 ms; arrow head is pharyngeal muscle, arrow is laryngeal muscle). (Courtesy Dr. Simon Platt.)

decremental response to supramaximal repetitive nerve stimulation. This should be performed only if the dog is stable and aspiration pneumonia is under control. In most cases electrodiagnostics do not provide a specific diagnosis but can indicate whether the underlying disease process is myopathic or neuropathic and the pattern of muscle and peripheral nerve involvement. A complete discussion of electrodiagnostic testing is described elsewhere (Cuddon, 2002).

Muscle and Nerve Biopsies

The goal of diagnostic testing is to identify a specific disease and formulate a treatment plan. With the exception of MG, which is best diagnosed by the serum AChR antibody titer, and the congenital myotonias, which are identified by electromyography, the muscle biopsy and in some cases the peripheral nerve biopsy are the only ways to reach a specific diagnosis. If the problem is in the muscle or nerve, go to the source of the problem. As with most treatable neuromuscular diseases, the goal is to reach an accurate diagnosis early in the course of the disease, before fibrosis and myofiber loss is extensive and treatment options become few. In cases of pharyngeal dysphagia, a biopsy should be obtained from a pharyngeal muscle if possible, in addition to a biopsy from a large proximal pelvic limb muscle such as the vastus lateralis or a thoracic limb muscle such as the triceps muscle.

If a pharyngeal muscle biopsy is not possible, a limb muscle biopsy may provide the diagnosis. A complete discussion of how to correctly collect and prepare muscle and nerve biopsy specimens is described elsewhere (Dickinson and LeCouteur, 2002).

TREATMENT

The treatment of oropharyngeal dysphagias depends on the underlying cause and whether the condition is congenital or acquired and morphologic or functional. Unfortunately an underlying cause in cases of congenital dysphagia is only rarely found. Very little information is in the literature accurately describing these disorders, but most are likely neurogenic in origin. If a failure of relaxation of the cricopharyngeal muscle can be identified, a myotomy may be of benefit. If there is asynchrony between the pharyngeal constrictors and relaxation of the cricopharyngeal muscle, a myotomy is contraindicated. If a morphologic disorder is identified such as stricture, foreign body, neoplasia, or structural abnormality, treatment should be directed to the specific abnormality. In my experience the majority of cases of dysphagia occur in mature animals, are acquired, and are associated with an underlying neuromuscular disease. Many of the neuromuscular diseases such as MG and polymyositis are treatable; thus an early diagnosis and appropriate therapy should increase the chances of a

positive clinical outcome. In inflammatory myopathies, once muscle mass is lost and fibrosis is significant, the chance of regaining normal muscle mass and function is poor. If severe aspiration pneumonia is present, the prognosis is also poor for recovery. Specific treatments for MG, inflammatory myopathies, and other neuromuscular diseases are covered in Chapters 241 and 242.

In all cases supportive care is important, but particularly for the pharyngeal dysphagias in which aspiration pneumonia is a risk. If aspiration pneumonia is identified, specific respiratory therapy should be initiated (Chapter 149). Appropriate fluid and nutritional support should be provided, and a gastrostomy tube should be placed if necessary to provide adequate nutrition and lessen aspiration pneumonia.

PROGNOSIS

The prognosis depends on early recognition of dysphagia, identification of an underlying cause, and the presence of a treatable disease. Although the most common causes of acquired dysphagia such as MG, myositis, and possibly the endocrine myopathies associated with hypothyroidism and Addison's disease are treatable, they must be diagnosed early in the course of the disease for the best clinical outcome. Many neuromuscular diseases are not treatable, such as the muscular dystrophies and most of the peripheral neuropathies, and the prognosis for recovery is poor in these cases. Aspiration pneumonia and severe debilitation may present fatal complications.

CHAPTER 111

Esophagitis

MICHAEL D. WILLARD, *College Station, Texas*
ELIZABETH W. CARSTEN, *Oro Valley, Arizona*

PATHOPHYSIOLOGY

Esophagitis (inflammation of the esophageal mucosa) is most often caused by gastric acid, other caustic substances, or trauma (e.g., foreign objects). Of these, gastric acid is probably the most common cause of clinically serious esophagitis. Esophagitis can develop when the esophageal mucosa is exposed to excessive acid because of gastroesophageal reflux (GER), frequent vomiting of gastric acid (e.g., parvoviral enteritis), or production of greater than normal amounts of acid (e.g., gastrinoma). In GER gastric contents move into the esophagus unrelated

to vomiting. Normal animals experience occasional GER without harm because esophageal peristalsis quickly returns acid to the stomach. However, severe mucosal damage may ensue when acid persists in or repeatedly enters the esophagus. For example, chronic esophagitis caused by spontaneous GER is well reported in cats (Han, Broussard, and Baer, 2003; Gualtieri and Olivero, 2006), and it is usually the result of hiatal hernia or lower esophageal sphincter (LES) abnormalities.

Anesthetized animals are a special case because acid can linger in the esophagus for minutes to hours. Anesthesia-

associated reflux appears to be an important cause of esophagitis and stricture formation, with approximately 65% of esophageal strictures being attributed to anesthetic-associated esophagitis in two studies (Melendez et al., 1998; Leib et al., 2001). The choice of preanesthetic and anesthetic agents, length of preoperative fasting, age, and intraabdominal versus extraabdominal procedures may influence the incidence of intraoperative GER (Wilson and Walshaw, 2004), but esophagitis caused by anesthesia-associated GER occurs erratically and unpredictably.

Nonacid damage may include drug-induced esophagitis, especially from doxycycline (Melendez, Twedt, and Wright, 2000). Cats occasionally lick caustics (e.g., benzalkonium chloride) off of their fur, sustaining oral and esophageal lesions. Bones and fishhooks are probably the most common canine esophageal foreign objects, but they seldom cause strictures because they typically produce only focal inflammation. Recently there have been anecdotal reports of chew treats causing circumferential damage in the canine esophagus, and cats occasionally have hairballs that can cause a similar lesion. Finally the esophagus may be infected primarily (e.g., pythiosis) or secondarily in immunodeficient patients (e.g., dogs being treated with steroids, azathioprine, or cyclosporin for immune-mediated disorders). Rarely an esophageal tumor causes mucosal inflammation.

When the esophagus becomes inflamed, motility can be impaired, allowing food to be retained and ultimately regurgitated. More important, poor esophageal motility allows acid refluxed into the esophagus to remain longer, worsening the esophagitis. LES dysfunction may occur secondary to esophagitis, allowing more GER. Chronic esophagitis caused by GER can be associated with severe histologic changes in the distal esophagus, including metaplastic changes somewhat comparable to Barrett's esophagus in humans (Gualtieri and Olivero, 2006; Han, Broussard, and Baer, 2003). If the mucosal damage is severe (e.g., penetrating to the muscularis), healing may be accompanied by cicatrix and esophageal stricture. Most strictures resulting from GER occur between the thoracic inlet and the diaphragm, where GER typically causes the most severe damage. Strictures cranial to the thoracic inlet are often secondary to foreign objects, but severe reflux can cause acid-induced injuries in this region.

CLINICAL SIGNS

The magnitude of clinical signs depends on the severity and depth of the esophageal inflammation and the presence and degree of stricture. Animals with esophagitis may regurgitate or be anorexic (ostensibly because of esophageal pain). The more severe the inflammation, the more severe is the anorexia. Blood is seldom present in regurgitated material. If a caustic agent was ingested, there might be contributory lingual and oral burns. Vomiting may be prominent in some patients, but in that case the esophagitis is usually secondary to the cause of the vomiting.

Signs of esophagitis secondary to anesthesia-associated GER often begin 1 to 3 days and occasionally up to 2 weeks after a causative anesthetic event (Wilson and Walshaw, 2004). Esophagitis may produce immediate (caused by inflammation) or delayed (caused by stricture) signs.

Animals with profuse vomiting may begin to regurgitate concurrently. Regurgitation in animals that were previously vomiting suggests that esophagitis has developed secondary to the vomiting and persistent exposure of the esophageal mucosa to excessive gastric acid. Animals with previously asymptomatic esophageal disease (e.g., mild esophageal dilation) that vomit (e.g., acute gastritis, foreign object) can retain substantial amounts of gastric acid in the dysfunctional esophagus. They may subsequently start regurgitating because of the resulting esophagitis.

Clinical signs of stricture depend on the degree of obstruction. In general, the narrower the stricture, the more pronounced is the regurgitation. Animals with mild-to-moderate obstruction often ingest and retain liquids (if not drunk too fast) and sometimes soft foods (if eaten slowly and in small amounts). Obstructions closer to the mouth usually cause more immediate regurgitation because of the smaller esophageal luminal reservoir proximal to the obstruction. Pain may occur if the esophagus is forcefully pushing a food bolus against a stricture. Modest obstructions may cause no signs until the patient attempts to swallow a large food bolus or foreign object. Sometimes there is obvious progression in severity as the stricture matures and contracts, causing greater obstruction.

DIAGNOSIS

Esophagitis or esophageal stricture may be suspected from the history (as described previously) or from clinical circumstances. Survey thoracic radiographs are seldom diagnostic; esophageal dilation is often minimal or absent. Mediastinal or pleural air or fluid may indicate perforation. Contrast radiographs are often diagnostic of strictures but are unreliable in detecting inflammation. If perforation seems likely (e.g., pneumothorax or septic pleural effusion), contrast films are seldom needed. But, if one is unsure and believes the contrast study is indicated, an iodinated contrast agent should be used instead of barium. Otherwise barium often provides a more definitive study.

Esophagitis is suggested by an irregular esophageal mucosa with some retention of barium. Liquid barium may quickly pass through a partial stricture, making it easy to miss the obstruction, even when using fluoroscopy. Nonetheless, liquid barium should be administered first so that any aspiration will produce minimal morbidity. If no lesions are detected using liquid barium, barium mixed with canned food (this should be a relatively solid consistency as opposed to a more liquid form) should be used next. Fluoroscopy is preferred over static images because it may reveal partial obstructions not seen with the latter (i.e., a bolus may "squeeze" through a partial stricture in the period between the bolus being eaten and the radiograph being obtained). Barium paste offers no substantive advantage and should be avoided.

Hiatal hernia can be easy or extremely difficult to diagnose. Some animals have obvious abnormalities on plain thoracic radiographs, whereas others have normal barium contrast studies, even when fluoroscopy is used. Diagnosis may require administering liquid barium and viewing the LES area fluoroscopically while applying pressure to the abdomen. This maneuver may force the gastric fundus through the hernia, confirming the

diagnosis. This technique may also reveal GER; however, it can be difficult to distinguish “innocent” from clinically significant reflux. Sometimes endoscopy is the most sensitive way to diagnose hiatal hernia.

Endoscopy is the most *sensitive and specific* way to detect esophagitis. Erythema, friability, bleeding, erosions, and exudative pseudomembranes usually are obvious. The esophageal mucosa just aborad to the cricopharyngeal sphincter normally is a little rougher than the rest of the esophagus. Humans can have esophagitis that can only be diagnosed histopathologically, but such cases have not been well documented in dogs and cats. Nonneoplastic canine esophageal mucosa is difficult to biopsy adequately with flexible endoscopic biopsy forceps. Rigid forceps are often necessary to obtain a biopsy specimen of canine esophageal mucosa that is not obviously diseased. Distal feline esophageal mucosa is easier to sample with flexible forceps.

There are a few potential pitfalls when looking for strictures endoscopically. Although typically strictures are obvious at endoscopy, large dogs may have an esophageal stricture that decreases the luminal diameter by 50% or more and yet is missed by the endoscopist. The scope diameter can be so small when compared with the esophageal lumen of a larger-breed dog that the tip of the scope readily passes through a partial stricture without the operator noticing that the luminal diameter was diminished. This error is especially likely if the stricture is near the LES (i.e., the endoscopist believes that cicatrix is simply the normal LES). This is particularly significant because many strictures occur near the LES. When the tip of the endoscope cannot pass through a stricture, one cannot determine the extent of the stricture or if other strictures exist further aborad. Postanesthetic strictures in particular may be focal or extensive (up to 15 cm has been reported; Wilson and Walshaw, 2004), and there may be a poorer prognosis when attempting to dilate longer, more extensive strictures.

THERAPY

Inflamed esophageal mucosa usually heals if it is protected from further damage. Therefore it is important to eliminate predisposing factors (e.g., hiatal hernia), foreign objects, or predisposing drug therapy. Preventing further exposure to gastric acid is usually the crucial aspect. Esophageal mucosa is more easily damaged by acid than is gastric mucosa because the esophagus does not have a mucus-bicarbonate preepithelial barrier and does not heal by epithelial restitution (also see Chapter 114 on Gastric Ulceration). Furthermore, endogenous prostaglandins are not as effective in protecting the esophageal epithelial surface, and the esophagus does not produce a “mucus cap” after epithelial injury. Thus minute amounts of acid can severely damage the esophagus, and healing requires preventing additional vomiting or GER. Human esophagitis usually results from GER, and effective therapy requires prokinetic drugs to keep the stomach empty and/or drugs that lessen or eliminate acid secretion.

Metoclopramide (a prokinetic agent effective in the stomach) is minimally effective in preventing esophagitis caused by GER in humans, but cisapride (Propulsid, Janssen) was clearly beneficial before its use in humans

was curtailed because of adverse cardiac effects. Cisapride was at least as effective as histamine-2 (H_2) receptor antagonists, and cisapride plus an H_2 receptor antagonist was more effective than the latter by itself. The main disadvantage of cisapride therapy is that it is administered orally (and hence may never reach the stomach in regurgitating patients), whereas metoclopramide may be given parenterally. Cisapride was particularly effective in preventing recurrence after esophagitis had been brought under control. We prefer cisapride at 0.25 mg/kg every 8 to 12 hours and use metoclopramide if cisapride cannot be administered successfully.

H_2 receptor antagonists inhibit gastric acid secretion, thus diminishing the volume that can be refluxed into the esophagus. These drugs are competitive inhibitors of gastric acid secretion (see Chapter 114). Although effective in treating milder forms of human esophagitis, they are not as useful in severe esophagitis. This is probably because H_2 receptor antagonists may increase the gastric pH only to between 4.0 and 5.0, which, although effective in treating gastric ulcers, may be inadequate for esophageal disease. Using larger and more frequent doses of more potent H_2 receptor antagonists is more effective in humans because of greater suppression of acid secretion. The same is probably true in dogs and cats, but objective data are lacking. In humans H_2 receptor antagonists that have gastric prokinetic activity (e.g., nizatidine) may be more effective than those that do not (e.g., cimetidine, famotidine) (Hamamoto et al., 2005).

Proton pump inhibitors are noncompetitive and diminish gastric acid secretion to a much greater degree for a much longer time than do the H_2 receptor antagonists. The two most commonly used proton pump inhibitors in the United States are omeprazole and lansoprazole. Therapy with omeprazole can produce near anacidity in the stomach and refluxed material. Consequently these drugs may be effective in patients that are resistant to H_2 receptor antagonists. We prefer omeprazole 0.7 to 2 mg/kg every 12 to 24 hours. Once- or twice-daily therapy lends itself to greater client compliance than does the schedule of every 6 to 8 hours required with some H_2 receptor antagonists. Omeprazole is recommended primarily when severe esophagitis occurs or is anticipated. The medical therapy that we prefer in severely affected patients has been a combination of cisapride and omeprazole. Unfortunately omeprazole is given orally and may be regurgitated before it reaches the stomach, and it requires 2 to 5 days to attain maximal gastric acid suppression. We generally use H_2 receptor antagonists if oral omeprazole cannot be administered successfully or if one cannot wait 2 to 5 days for maximal gastric acid suppression. Lansoprazole is at least as effective as omeprazole in humans, and there are anecdotal reports of its use in dogs (1 mg/kg, IV, every 24 hours) and cats.

A gastrostomy tube is recommended to ensure adequate nutrition while minimizing esophageal mucosal irritation. These tubes also allow administration of cisapride and omeprazole with confidence. Esophagostomy and pharyngostomy tubes may perpetuate esophageal inflammation (via continued contact between the tube and the ulcerated mucosa) and are not recommended. Aggressive medical management (i.e., cisapride, omeprazole, and

gastrostomy feeding tube) is strongly recommended for patients with severe disease or inflamed strictures.

Orally administered sucralfate has been used for esophagitis. Although this therapy intuitively makes sense, studies in humans have usually demonstrated minimal or no benefit. One probably must time the sucralfate administration to coincide with high acid levels in the otherwise neutral esophagus if sucralfate is to function as desired. Therefore there is some rationale for administering sucralfate and hoping that, if GER occurs, the sucralfate will be carried back into the esophagus, where it will be effective because of the now acid esophageal environment.

Corticosteroids are often administered systemically to try to prevent stricture formation; however, they are of uncertain efficacy. Humans ingesting caustic agents such as sodium hydroxide (which causes an extremely severe lesion) are not clearly benefited by such therapy and might be at increased risk of infection. However, dogs and cats seldom have such a severe lesion, and they might benefit. Antibiotics are often used to protect denuded esophageal mucosa from bacterial infection. Although antibiotics intuitively seem indicated in these patients, they have not clearly aided the healing of esophagitis. If antibiotics are used, one should choose broad-spectrum drugs that are also effective against the anaerobic bacteria that are commonly found in the oral cavity (e.g., *Prevotella* spp., *Porphyromonas* spp., *Fusobacterium* spp., *Bacteroides* spp.).

Ballooning and bougienage are used to eliminate strictures. Surgical resection of esophageal strictures should be considered only as a last-ditch, salvage option because strictures commonly recur at the surgical site. Bougienage allows more force to be applied to the stricture than is possible with a balloon, which is important for patients with large amounts of thick, fibrous cicatrix that balloons cannot break down and for strictures so small that balloons cannot be inserted through them. Studies in humans suggest that bougienage is about as effective and safe as balloon dilation. Bougienage can be more traumatic and cause perforation; however, side effects and complications seem more operator dependent than technique dependent. Ballooning may be less likely to cause esophageal perforation, especially when bougienage is performed by an inexperienced operator. However, neither technique is completely safe. If ballooning is chosen over bougienage, the procedure is best performed by using over-the-wire or through-the-scope esophageal balloons. Flexible guidewires seem to reduce the risk of iatrogenic esophageal trauma from the tip of the catheter cutting into the esophagus during inflation.

The endoscopist should visualize the stricture site while it is being dilated. It is important to minimize the amount of trauma so as to minimize the likelihood of stricture recurrence. In particular one should avoid creating deep fissures and removing mucosa from the site (something that is easy to do when aspirating blood or moving the endoscope back and forth through the site). It is often better to plan on several less aggressive procedures in animals with extensive strictures, each causing minimal trauma, as opposed to attempting one aggressive dilation that ultimately causes more trauma, making stricture recurrence more likely. In general two-to-four dilation procedures are typically needed (Melendez et al.,

1998; Leib et al, 2001; Wilson and Walshaw, 2004), but 10 to 15 may be needed in some difficult cases. In some difficult cases mild dilation is performed two to three times weekly in an attempt to maintain patency of the stricture site while causing as little trauma as possible. Intralesional steroid injection and three or four quadrant notchings of the stricture before dilation may be considered in severe cases. Intralesional steroid injection seems to have a place in the treatment of difficult-to-resolve benign strictures in humans (Altintas et al, 2004). Finally, overinflation of the esophagus should be avoided lest tension pneumothorax develop from esophageal rupture.

The esophagus should be evaluated gently after the procedure to detect excessive iatrogenic trauma. The thorax should be radiographed after difficult procedures or if there is any hint of respiratory difficulty to detect pneumothorax secondary to esophageal rupture. Conservative medical care (which may include gastrostomy and/or chest tubes) often allows healing if the esophagus is excessively traumatized or if pneumothorax develops.

Patients with esophagitis caused by ongoing acid reflux should usually be reexamined by endoscopy again after 5 to 8 days of medical therapy, and oral feeding reinitiated if the esophagus has healed. After the patient is able to eat normally without regurgitating, medical therapy can be tapered or perhaps discontinued. If the esophagitis was the result of a nonrecurring cause (e.g., foreign body), repeat endoscopy is usually unnecessary unless signs of dysfunction persist. Animals in which strictures were dilated may be reexamined endoscopically 5 to 7 days after the procedure. However, if the patient is eating without difficulty, a repeat endoscopy is probably unnecessary, although rare patients have stricture recurrence weeks to months later. Patients with stricture plus severe esophagitis and those with very extensive, long strictures should be closely monitored because these are usually the most difficult to manage. Repeat endoscopic procedures are usually important in such patients. Occasionally additional strictures arise (usually close to the LES) while the first one is being treated. Patients that have severe strictures or ones that continually recur after ballooning might benefit from intralesional injection of steroids (Altintas et al., 2004). The goal is not necessarily to eliminate the stricture altogether but rather to achieve an esophageal lumen that is large enough to allow the animal to eat without regurgitating (although this sometimes means feeding softened foods).

PROGNOSIS

Prognosis typically depends in part on the underlying cause. Animals with GER secondary to congenital hiatal hernias often require surgical correction, but their prognosis is usually reasonably good. There is currently no evidence that animals experiencing anesthesia-induced GER and subsequent stricture are at increased risk for recurrence if reanesthetized. If the animal is treated before the inflammation is severe enough to cause a stricture, the prognosis is usually better. Strictures accompanied by substantial inflammation seem more difficult to resolve, and the owners should be prepared for multiple dilation procedures. Typically animals with severe inflammation are

salvageable if the owner can afford the multiple procedures that may be necessary. Success rates of 77% to 88% have been reported in animals undergoing stricture dilation, depending on the definition of success (Melendez et al., 1998; Leib et al., 2001; Wilson and Walshaw, 2004). If the esophageal stricture cannot be resolved or if the stricture is caused by terminal malignancy, a permanent, low-profile gastrostomy device may palliate the patient. Esophageal stents can have more problems in dogs and cats than in humans because of the change in direction of the esophagus at the thoracic inlet.

CHAPTER 112

Canine Megaesophagus

BETH M. JOHNSON, *Knoxville, Tennessee*
 ROBERT C. DeNOVO, *Knoxville, Tennessee*
 ERICK A. MEARS, *Tampa, Florida*

Symptoms of esophageal disease occur when esophageal motility is disturbed or when there is obstruction to the movement of ingesta. Swallowing becomes difficult, even painful, and food will not go down. Regurgitation, dysphagia, and ptyalism are common signs; and aspiration pneumonia is a frequent complication. Typically both liquid and solid foods pass poorly with motility disturbances of the esophagus, whereas liquids often pass easily with obstruction of the esophagus. A thorough physical examination and often an extensive diagnostic workup are necessary for determining the cause of esophageal disease and designing a treatment plan. Box 112-1 lists the primary causes of esophageal dysfunction in the dog.

FUNCTIONAL ANATOMY

The esophagus is not simply a tube through which food passes. It is an organ with complex innervation and patterns of motility designed to transport fluid and food efficiently from the pharynx to the stomach. The esophagus begins at

the pharyngoesophageal junction, commonly referred to as the upper esophageal sphincter (UES), which prevents reflux and aspiration of ingesta from the esophagus. The body of the canine esophagus consists of two layers of skeletal muscle that propel ingesta to the stomach. The gastroesophageal junction, referred to as the lower esophageal sphincter (LES), is the distal limit of the esophagus and prevents reflux of gastric content into the esophagus.

The UES separates the pharynx from the cervical portion of the esophagus and is formed by the cricopharyngeus and thyropharyngeus muscles dorsolaterally and the cricoid cartilage ventrally. These striated muscles are innervated by the glossopharyngeal, pharyngeal, and recurrent laryngeal branches of the vagus nerve that originate in the brainstem nucleus ambiguus. The muscles of the sphincter remain contracted at all times, except during a swallow, when they relax momentarily to allow passage of a bolus. The muscles contract promptly to maintain closure of the sphincter and protect against esophagopharyngeal reflux and aspiration.

- Bronchoesophageal fistula

In contrast to the feline esophagus that is composed of smooth muscle in the distal one third, the canine esophageal body is composed entirely of two oblique layers of skeletal muscle and is innervated by the somatic branches of the vagus nerve. The LES is a physiologic sphincter rather than a true anatomic sphincter because it does not consist of a distinct muscle mass. It consists of an outer layer of longitudinal striated muscle and an inner layer of circular smooth muscle that merge with the smooth muscle of the stomach. The LES remains closed except to allow passage of a bolus. Competence of the LES is maintained by the gastric rugal folds, the muscular sling of the right crus of the diaphragm, the oblique angle of the gastroesophageal junction, and gastric compression on the esophagus. This sphincter separates the esophagus from the cardia of the stomach and allows ingesta to pass into the stomach while preventing reflux of stomach content into the esophagus. Cholinergic, nonadrenergic noncholinergic, and myogenic mechanisms all play a role in maintaining gastroesophageal sphincter tone. Increases in tone, which serve to protect the esophagus from gastroesophageal reflux, are mediated by moderately increased intragastric pressure; acid in the cardia; high-protein diet; and a number of hormones such as gastrin, histamine, and acetylcholine (ACh). Conversely, marked increases in intragastric pressure decrease sphincter tone to facilitate eructation and prevent gastric rupture.

Esophageal contraction occurs in response to swallowing (primary peristalsis) and esophageal distention (secondary peristalsis). The oropharyngeal phase of swallowing and the movement of food through the UES initiate primary peristalsis. Afferent vagal receptors in the pharynx and proximal esophagus are stimulated by the

presence of food; solids are more effective than liquid in stimulating a swallowing reflex. The origin of the vagus nerve, the nucleus ambiguus for striated muscle, initiates an efferent response via the somatic nerve fibers of the vagus. This neuronal pathway ends at the myoneural junction with a coordinated contraction of the UES and propagation of a peristaltic wave aborally along the body of the esophagus, through the LES, and into the stomach. Remaining intraluminal ingesta within the esophagus stimulate esophageal afferent receptors to initiate a secondary peristaltic wave to clear the lumen. Any disease or lesion affecting any part of this neuromuscular pathway can alter normal esophageal motility and cause megaesophagus (Box 112-2).

MEGAESOPHAGUS

Megaesophagus is a condition characterized by decreased or absent esophageal motility that usually results in diffuse dilation of the esophagus. Megaesophagus occurs as a congenital disorder that becomes clinically apparent at or shortly after weaning, or it can occur as an acquired disorder in a previously normal adult. Acquired megaesophagus can be secondary to a variety of diseases that cause neuromuscular dysfunction, or it can occur as a primary disorder for which the cause is unknown (idiopathic megaesophagus).

Congenital Megaesophagus

Congenital megaesophagus occurs in both pure and mixed-breed dogs. It is known to be inherited in the wire-haired fox terrier as an autosomal-recessive trait and in the miniature schnauzer as either an autosomal-dominant or autosomal-recessive trait with partial penetrance. Congenital megaesophagus occurs with increased prevalence in Great Danes, German shepherds, Labrador retrievers, Newfoundlands, Chinese shar-peis, and Irish setters. Although not proved, the predilection for megaesophagus in these breeds, in addition to reports of entire litters of German shepherds, Great Danes, Newfoundlands, and shar-peis being affected, suggests that a hereditary basis for megaesophagus exists. For this reason owners are best advised not to use affected dogs or those closely related to affected dogs for breeding. Clinical signs usually occur by 3 months of age; however, dogs with mild symptoms might not be presented until 1 year of age.

Although the pathogenesis of congenital megaesophagus is unclear, esophageal function studies of affected dogs indicate defects in the vagal afferent innervation of the esophagus. Other studies have confirmed that vagal efferent innervation in affected dogs is normal but that esophageal motor function is decreased, possibly secondary to abnormal biomechanical properties of the esophageal muscle.

Acquired Megaesophagus

Acquired megaesophagus can occur in any breed; however, it is worthy to note that the breeds at a significantly increased risk for developing the disease include some of the same breeds discussed previously (i.e., German shepherd dogs, golden retrievers, Irish setters, and Great Danes). Secondary megaesophagus can be caused by any disorder that inhibits esophageal peristalsis either by disrupting esophageal neural pathways or by causing esophageal muscular dysfunction. Numerous central and peripheral neuropathies, diseases of the neuromuscular junction, and myopathies have been reported to cause megaesophagus (see Box 112-2). Most of these diseases are uncommon, and an exhaustive search to rule out all is unrealistic. However, several diseases should routinely be considered.

Myasthenia gravis (MG) is the most common cause of acquired megaesophagus in the dog (also see Chapter 241). It occurs rarely as a congenital disease and more frequently as an acquired disease; both can cause megaesophagus. Acquired MG is an autoimmune disorder that interferes with normal neuromuscular transmission. Production of autoantibodies against nicotinic ACh receptors decreases the number of receptors available for normal neuromuscular transmission,

resulting in skeletal muscle weakness. Two forms of acquired MG, generalized and focal, have been identified. Generalized MG causes exercise-related generalized muscle weakness that worsens after exercise and improves with rest. Most dogs with generalized MG also have megaesophagus. Focal MG causes weakness that predominantly affects esophageal, pharyngeal, or facial muscles. Affected dogs are usually presented to the clinician with symptoms of megaesophagus.

Diagnosis of MG is made by measuring increased antibody titers to ACh receptors, but it is important to be aware that serum ACh receptor antibody concentrations tend to be lower in focal MG than in the generalized form. ACh receptor antibodies are negative in up to 15% of generalized MG and up to 50% of focal MG in humans (Dewey, 1997). Seronegative myasthenics exist in the veterinary population as well. Approximately 2% of dogs with generalized myasthenia gravis are seronegative. The percentage of dogs with seronegative focal myasthenia gravis has not been determined (Shelton, 2002). Immunocytochemical staining, which localizes the immune complexes at the neuromuscular junction after incubation of patient serum with normal canine muscle, is a second diagnostic method that is also relatively inexpensive and easy to perform. This test is not specific for antibodies against the ACh receptors; thus a positive result is not definitive. However, it is a useful screening test.

Many dogs diagnosed as having "idiopathic" megaesophagus are likely to have focal MG. In a study by Shelton and associates (1990), serum samples from 152 dogs with idiopathic megaesophagus were tested for ACh receptor antibodies. Results confirmed that 40 of 152 (26%) had antibody titers diagnostic for MG. Another 17 cases (11%) that did not have positive titers had positive immunocytochemical staining of immune complexes. Of those affected, 48% had clinical improvement or remission of clinical signs with treatment.

Occasionally megaesophagus is observed in dogs with primary, secondary, or atypical hypoadrenocorticism. Impaired muscle carbohydrate metabolism and depletion of muscle glycogen stores resulting from glucocorticoid deficiency and decreased catecholamine activity have been suggested as possible causes. Megaesophagus has been reported to resolve with prednisone treatment in dogs with glucocorticoid-deficient hypoadrenocorticism (Bartges et al., 1992).

Hypothyroidism has historically been cited as a possible cause of megaesophagus. However, a definitive association between hypothyroidism and megaesophagus has not been proved. In a case-controlled study by Gaynor and associates (1997) of 136 dogs with acquired megaesophagus, 272 control dogs from the general hospital population, and 151 control dogs that underwent thyroid-stimulating hormone response tests, no association between megaesophagus and hypothyroidism was found. In one retrospective study of 29 hypothyroid dogs, four had megaesophagus; one dog showed clinical improvement in esophageal symptoms when treated with thyroid supplement. Radiographic evidence of a dilated esophagus persisted in all four dogs (Jaggy et al., 1994). There is an association between MG and hypothyroidism, most likely caused by a common immune-mediated disorder. Therefore thyroid function should still be evaluated in dogs with megaesophagus until MG has been definitively ruled out.

Dysautonomia, an idiopathic condition that results in clinical signs attributable to failure of the sympathetic and parasympathetic nervous systems, is becoming a more common cause of megaesophagus. Dysautonomia typically affects young dogs from rural environments with the freedom to roam. Clinical signs are consistent with autonomic dysfunction and include vomiting, regurgitation, weight loss, dysuria, decreased anal tone, mydriasis with absent pupillary light reflexes, decreased tear production, and dry mucous membranes. Greater than 60% of patients with dysautonomia have radiographic evidence of megaesophagus; 71% of those have concurrent lung disease (Detweiler, 2001). Radiographic evidence of megaesophagus with dysautonomia is indistinguishable from that seen with other causes of megaesophagus; however, gastric motility should be normal with causes other than dysautonomia.

Another condition that should prompt evaluation for megaesophagus is laryngeal paralysis. Laryngeal paralysis may be a risk factor for acquired megaesophagus because both diseases have a common pathogenesis involving the vagus nerve. The vagus nerve may be the only affected nerve, or it may be affected as part of a diffuse polyneuropathy. Similarly, dogs with histories of chronic or recurrent gastric dilation with or without volvulus should be evaluated for megaesophagus. In these cases LES obstruction or esophagitis secondary to vomiting is the proposed mechanism for acquired megaesophagus.

Idiopathic Megaesophagus

Idiopathic megaesophagus is a severe and often fatal disease characterized by a large dilated esophagus with no apparent motility. It occurs spontaneously, usually in large-breed adult dogs between 5 and 12 years of age. There appears to be no sex or breed predisposition. Unfortunately the majority of adult dogs with megaesophagus are diagnosed as having idiopathic megaesophagus. The etiopathogenesis of this disorder is unknown; however, recent studies have clarified that the abnormality appears to be neurogenic rather than myogenic. Manometric studies have shown that the function of the UES and LES is normal in response to a swallow, indicating that the efferent innervation is intact. However, when the esophagus is distended with an intraluminal balloon to initiate secondary peristalsis, compliance of the esophagus is increased compared to normal dogs, the UES and LES fail to relax as in normal dogs, and inhibition of diaphragmatic electromyographic activity does not occur as in normal dogs. These observations indicate a defect of either afferent sensory innervation of the esophagus or esophageal muscle function (Tan and Diamant, 1987; Holland et al., 1996).

Clinical Signs

Regurgitation is the most common clinical sign observed with megaesophagus. Most owners fail to recognize the difference between regurgitation and vomiting and report vomiting as the primary complaint. The clinician must differentiate between these clinical signs to ensure proper localization and diagnosis of the problem. Regurgitation is characterized as a passive evacuation of fluid, mucus, and undigested food from the esophagus. No consistent temporal relationship occurs between eating and regurgitation

caused by esophageal disease. Other signs observed with megaesophagus include ptyalism, halitosis, and vomiting. Cough, nasal discharge, and dyspnea caused by aspiration pneumonia are frequent presenting complaints, especially in young or debilitated dogs. Some dogs appear normal on physical examination, whereas others are underweight to cachectic from poor nutritional intake, depending on the duration and severity of disease. Puppies with congenital megaesophagus are usually smaller than their littermates. Swelling of the ventral neck near the thoracic inlet from esophageal distention with ingesta is present occasionally. Other clinical signs may reflect diseases causing secondary megaesophagus. Careful examination should be performed for neuromuscular disease such as muscle weakness, pain, or neurologic deficits.

Diagnosis

Diagnosis of megaesophagus is based on radiographic identification of a dilated or hypomotile esophagus. Survey thoracic radiographs confirm the presence of generalized megaesophagus in most cases and usually reveal an esophagus dilated with air, fluid, or ingesta. In equivocal cases with mild or segmental dilation or if hypomotility without dilation is suspected, a contrast esophagogram is indicated. Barium liquid and barium meal contrast studies must be performed to detect subtle hypomotility and to rule out a stricture, foreign body, or other obstructive lesion. Although the availability of fluoroscopy in practice is limited, esophageal motility can be assessed well with static contrast radiographs during and immediately after a swallow of contrast material. Esophageal retention of any contrast material in a dog that is symptomatic for esophageal disease is abnormal. Radiographic signs of aspiration pneumonia, even in the absence of clinical or radiographic signs of esophageal disease, should alert the clinician to the potential for esophageal disease and the need for a contrast esophagogram. Dogs that have significant retention of contrast material in the esophagus are at risk for severe aspiration. They should be held in a vertical position for 5 to 10 minutes after the procedure and closely observed for at least an additional 30 minutes.

Esophageal motility is best evaluated using fluoroscopic, manometric, or scintigraphic procedures, which are usually limited to referral practices and teaching hospitals. Fluoroscopy provides visualization of swallow dynamics and helps to identify anatomic abnormalities of the esophagus. Manometry and scintigraphy provide quantitative measures of esophageal motility. Manometry is most useful to evaluate subtle motility abnormalities that are not evident on fluoroscopy. Manometry uses a catheter passed into the esophageal lumen for dynamic measurement of esophageal pressures, transit rate, and lower esophageal pressures during a swallow. Scintigraphy is a newer quantitative technique used to measure the transit time of a radiolabeled food bolus as it moves through the esophagus. Scintigraphy has the advantage of evaluating the response of the esophagus to a normal bolus in an awake patient without the influence of foreign material such as barium or an esophageal catheter.

Once the presence of megaesophagus has been confirmed, the clinician must determine whether the disorder is primary (idiopathic) or secondary. Generally most dogs with idiopathic megaesophagus have a very large, dilated, aperistaltic esophagus. Contrast material is slow to move into the stomach and may not do so for hours. Dogs with secondary

megaesophagus are often not as severely affected and have less dilation and some motility. A recent study to evaluate whether dogs with megaesophagus secondary to myasthenia gravis had less esophageal dilatation radiographically than dogs with other causes of megaesophagus documented a small, but significantly increased esophageal diameter in nonmyasthenic dogs. However, due to large overlap in values, the finding offers limited clinical utility (Wray and Sparkes, 2006).

Formulating a logical and economic diagnostic plan can be challenging. The initial diagnostic plan should be broad and include a complete blood count; a serum chemistry profile that includes a creatine kinase determination, electrolyte determination, and urinalysis; and a fecal examination. Results of these tests help determine which additional diagnostic tests should be considered. A complete blood count might provide a clue to the presence of hypoadrenocorticism, immune-mediated disease, lead toxicosis, or pneumonia. Serum chemistry profiles are useful to detect hypoadrenocorticism or myositis. Proteinuria is supportive of the diagnosis of systemic lupus erythematosus, and a fecal examination might identify *Spirocerca lupi* in dogs from endemic areas. Patients with congenital or idiopathic megaesophagus generally have few if any laboratory abnormalities.

If results of the initial diagnostic tests are inconclusive, an ACh receptor antibody test should be performed to rule out focal or generalized MG. The immunoprecipitation radioimmunoassay (Comparative Neuromuscular Laboratory, University of California at San Diego, La Jolla, CA) is a specific and sensitive test. When the index of suspicion for MG is high, but a diagnosis is not confirmed with ACh receptor antibody serology, a motor point muscle biopsy may be submitted to the aforementioned laboratory for immunocytochemical staining. This test is less specific for MG but is highly suggestive for diagnosing seronegative myasthenics. Although hypoadrenocorticism is infrequently associated with megaesophagus, this disease is a potentially treatable cause of megaesophagus. Dogs with unexplained acquired megaesophagus should have adrenal function (adrenocorticotrophic hormone stimulation test) evaluated. Furthermore, because of an indirect association to megaesophagus through association with other polyneuropathies such as MG, hypothyroidism should be ruled out with thyroid hormone evaluation. If gastric hypomotility is also suspected on radiographs, several simple pharmacologic tests can aid in an antemortem diagnosis of dysautonomia. Affected dogs should develop miosis in response to ocular installation of dilute (0.1%) pilocarpine solution, have no change in heart rate after administration of atropine, and have no flare response to intradermally administered histamine (Berghaus, 2001; Harkin, 2002).

Esophagoscopy usually is not helpful in determining the cause of megaesophagus. It is indicated if an obstructive lesion or foreign body is suspected but not confirmed by radiographs and to confirm the presence of esophagitis.

Other tests should be considered for individual cases if specific clinical signs or results of preliminary laboratory tests or both indicate the presence of a toxic, neurologic, or muscular disease. Lead, thallium, and anticholinesterase toxicities can be diagnosed by history, clinical signs, and toxicologic assay. Serum creatine kinase determinations, electromyography, and muscle biopsy are used to confirm the presence of myopathy or myositis. Systemic lupus erythematosus is diagnosed by the presence of systemic signs and positive antinuclear

antibody or lupus erythematosus tests or both. Laryngeal paralysis can be diagnosed with direct laryngeal examination. Symptoms of central nervous system disease can be evaluated with distemper titers, cerebrospinal fluid analysis, computed tomographic brain scans, or a combination of these methods. Such diseases are infrequent causes of megaesophagus.

Treatment

The goals in the management of megaesophagus are to identify and treat the primary cause, decrease the frequency of regurgitation, prevent overdistention of the esophagus, provide adequate nutrition, and treat complications such as aspiration pneumonia and esophagitis. Dogs with secondary megaesophagus that can be treated specifically for underlying disease may show improvement of esophageal motility with time; however, responses are variable. Treatment of dogs in which an underlying cause cannot be found is entirely symptomatic.

Cases of focal and generalized MG are treated with long-acting anticholinesterase drugs. Either pyridostigmine bromide, 1 to 3 mg/kg orally every 8 to 12 hours, or neostigmine, 0.04 mg/kg intramuscularly every 6 hours (if oral medication is not tolerated), is effective. If pyridostigmine bromide is administered in the syrup form, it should be diluted at a 50:50 ratio in water to avoid gastric irritation (Shelton, 2002). Improvement of clinical signs accompanied by a decrease in ACh receptor antibody concentration indicates a positive response to treatment. Antibody concentrations should be checked every 4 to 6 weeks to determine the course of the disease and adjust therapy, since spontaneous remissions do occur in a large percentage of dogs. Treatment should be continued until serum antibody titers are within the normal range. If clinical remission does occur, esophageal dilation may completely resolve, and medication can be discontinued; however, relapses do occur. The time course until remission can vary from 1 month to longer than 1 year. Some dogs with focal MG progress to generalized MG, usually within several weeks of the initial onset of clinical signs. Myasthenia is an immune-mediated disease; thus in most cases immunosuppression with corticosteroid therapy or a steroid-sparing agent such as azathioprine may be warranted. A retrospective study by Bartges, Hansen and Hardy (1997) evaluated 30 dogs with acquired MG and megaesophagus and discovered that glucocorticoid therapy alone resulted in clinical remission in 67% of cases. Multiple case reports of myasthenics experiencing clinical remission and a decrease in ACh receptor antibody titer after therapy with azathioprine are also available (Dewey et al., 1999). Other immune-directed therapy includes plasmapheresis, the filtration of plasma to rid the body of circulating antibodies. Shelton and associates (1990) evaluated 53 dogs with MG and saw spontaneous clinical and immunologic remission in 89% of dogs treated with anticholinesterase therapy alone. Therefore the use of immunosuppressive therapy is somewhat controversial, and the decision must be made on a case-by-case basis. Aspiration pneumonia should be ruled out or treated before the use of immunosuppressants, and the patient monitored closely for signs of developing infection.

Megaesophagus associated with hypoadrenocorticism resolves with corticosteroid and mineralocorticoid replacement. Immune-mediated polymyositis and polyneuritis and systemic lupus erythematosus may respond

to immune suppression. Toxic causes of megaesophagus are treated by removal of the offending agent or the use of specific antidotes or both. Treatment of dysautonomia is limited to symptomatic therapy, including cholinergic drugs to relieve some of the signs of parasympathetic dysfunction, such as bethanechol to improve bladder function and pilocarpine to relieve photophobia. Artificial tears and humidifying the air can help eliminate the dryness associated with eyes and oral and nasal mucous membranes. Symptomatic management of the associated megaesophagus is described in the following paragraphs. Despite supportive care, the prognosis for dysautonomia is poor.

The management of idiopathic megaesophagus, as well as most cases of megaesophagus resulting from neurologic disease, is entirely symptomatic and centers on special feeding techniques. A diet should be formulated using a high-calorie food to provide adequate nutritional intake. Meals should be fed in small portions several times daily and given to the dog in an upright position. This can be accomplished by placing the food on an elevated feeding platform or by simply holding the dog in a vertical position for several minutes after eating. Upright feeding provides surprisingly effective symptomatic control of regurgitation in many dogs. There is also an online support group (www.geocities.com/bailey_chair/) for megaesophagus dog owners as well as instructions on building a "Bailey chair" for upright feedings.

Because dogs with megaesophagus vary in their ability to swallow foods of various consistencies, the type of diet fed should be tailored for each patient. Liquefied foods tend to flow more easily with gravity than do solids, but liquids stimulate little peristaltic activity. Solids stimulate more peristalsis and perhaps pose less risk of aspiration. Barium contrast radiography using liquid, canned, and dry food might help determine the best consistency of food for a particular patient. Ultimately food trials are the best way of determining the consistency of food to be fed. In our experience, feeding small meatballs made of canned food provides the best symptomatic control.

Some dogs cannot tolerate oral feeding, especially if the esophagus is extremely distended, secondary esophagitis is present, or the patient is severely debilitated. Providing nutritional intake in these instances requires gastrostomy tubes for long-term feeding. Surgical, endoscopic, or nonendoscopic techniques for gastrostomy tube placement can be used. We have successfully managed the nutritional needs of large dogs with idiopathic megaesophagus for longer than 1 year using gastrostomy tube feeding. Esophagostomy tubes can exacerbate regurgitation and should not be used.

Aspiration pneumonia should be treated with broad-spectrum antibiotic therapy while culture and sensitivity results of a transtracheal wash are pending. Many dogs with megaesophagus appear to acquire esophagitis, which can worsen the clinical signs. Systemic antacid treatment with drugs such as ranitidine or omeprazole and protectant drugs such as sucralfate help control symptoms in some patients (see Chapter 111).

Many types of drugs have been used unsuccessfully in an attempt to improve motility and esophageal emptying in dogs with megaesophagus. Anticholinergic drugs and calcium channel blocking drugs such as nifedipine have been used to decrease LES pressure. Little if any response has been observed. Anecdotal observations indicate that some

dogs with megaesophagus improve clinically when treated with prokinetic drugs such as metoclopramide or cisapride. These observations have been questioned because metoclopramide and cisapride both increase motility by binding 5-HT₄ (serotonin) receptors on enteric cholinergic neurons, resulting in depolarization and contraction of gastrointestinal smooth muscle; canine esophagus consists of striated muscle. In normal dogs cisapride has actually been shown to decrease or slow the rate of transit of a food bolus through the esophagus (Mears, 1996). Therefore cisapride and other prokinetic drugs cannot be recommended to improve esophageal motility in dogs with megaesophagus.

If reflux esophagitis is suspected as a cause of esophageal hypomotility or a complication of megaesophagus, a trial with prokinetic drugs should be considered. These drugs do increase LES pressure, potentially decreasing episodes of reflux and subsequent esophagitis. However, this decision must be made carefully since increasing LES pressure can actually diminish esophageal clearance and perpetuate clinical signs in dogs with megaesophagus.

Bethanechol is a drug that has shown some promise in stimulating esophageal propagating contractions in some dogs affected with megaesophagus by directly binding to and stimulating cholinergic (muscarinic) receptors (Diamant and Szezepanski, 1974). This study was performed before the availability of testing for MG; thus it is impossible to know whether the documented improved motility is the result of treating megaesophagus secondary to undiagnosed MG or an indication that cholinomimetics can improve some cases of acquired idiopathic megaesophagus. There is still a population of undiagnosed myasthenics composed of both dogs that have not yet seroconverted and seronegative myasthenics. Therefore it is our opinion that dogs with acquired idiopathic megaesophagus should be treated as myasthenics with acetylcholinesterase inhibitors and immunosuppression as previously described.

Surgical treatment of congenital and idiopathic megaesophagus has not proved beneficial. Myotomy of the LES and techniques to plicate or resect the redundant esophagus may actually worsen the clinical signs. If radiographic evaluation of a patient shows failure of the LES to open and manometric studies confirm elevated sphincter pressures that did not relax in response to a swallow, a modified Heller's esophageal myotomy might be indicated.

Prognosis

The prognosis for megaesophagus is variable and difficult to predict. Successful outcomes depends on early diagnosis and aggressive dietary management. Even with diligent care, owners should be warned that aspiration pneumonia is a frequent and often fatal complication.

Congenital megaesophagus has at best a guarded prognosis for the animal to become a healthy and functional pet. Reported recovery rates vary from 20% to 46%. Some dogs improve with maturity, especially if the condition is recognized early and dietary management is begun before severe and irreversible dilation occurs. For example, most miniature schnauzers acquire improved or normal esophageal function by 6 to 12 months of age (Cox, 1980). There is one report of hypertrophic osteoarthropathy (HO), congenital megaesophagus, and no other pulmonary or

extrathoracic disease in a German shepherd (Watrous and Blumenfeld, 2002). This dog was euthanized at 6 years of age because of cachexia and HO, but in a single report of a human with achalasia and HO the bone changes regressed after successful surgical treatment of the achalasia. One proposed mechanism is a neurogenic basis in which chronic vagal dysfunction initiated a reflex arc leading to HO.

Adult-onset idiopathic megaesophagus has a poor prognosis. Some affected dogs respond to aggressive symptomatic management, but most die of aspiration pneumonia or are euthanized because of persistent regurgitation and debilitation within 5 months of the time of diagnosis. Spontaneous recovery rarely occurs.

The prognosis for dogs with secondary megaesophagus is good if the underlying disease can be treated successfully. This is especially true for MG in which clinical recovery can be expected to occur in at least 50% of the cases. Megaesophagus appears to respond well to corticosteroid therapy in dogs with hypoadrenocorticism. Megaesophagus secondary to dysautonomia carries a grave prognosis. Dogs with megaesophagus from polyradiculoneuritis, polymyositis, systemic lupus erythematosus, and botulism can recover esophageal function after successful treatment of the primary disease.

CHAPTER 113

Gastric *Helicobacter* spp. and Chronic Vomiting in Dogs

MICHAEL S. LEIB, Blacksburg, Virginia
ROBERT B. DUNCAN, Blacksburg, Virginia

Spiral bacteria were identified in the stomachs of humans and animals in the late 1800s. However, it was not until the early 1980s that Warren and Marshall proposed a relationship between *Helicobacter pylori* and gastric disease in humans. Soon after, studies demonstrated that spiral bacteria were common in the stomachs of clinically normal dogs and cats, as

well as those with signs of gastrointestinal (GI) disease. Experimental infection in both dogs and cats resulted in lymphoid follicular gastritis; however, clinical signs were absent or very mild.

Currently a direct causal relationship between spiral bacteria and chronic gastritis and vomiting has not been firmly established in dogs or cats. Based on several clinical

studies evaluating dogs and cats treated for *Helicobacter* spp. and identifying improvement or resolution of clinical signs, we believe that gastric *Helicobacter* spp. can cause or contribute to the clinical signs in some dogs with chronic gastritis and vomiting. This is supported by two published studies on the effects of treatment in dogs with clinical signs and gastric *Helicobacter* spp. (Happonen, Linden, and Westermarck, 2000; Leib, Duncan, and Ward, 2007).

We routinely determine if gastric *Helicobacter* spp. are present in all dogs and cats with chronic vomiting that undergo upper GI endoscopy. In most instances dogs and cats with gastric *Helicobacter* spp. and gastritis, with and without inflammatory bowel disease (IBD), are initially treated for *Helicobacter* spp. If clinical signs continue, dietary or antiinflammatory therapies for gastritis and IBD are instituted. We emphasize that, although the potential pathogenic role of gastric *Helicobacter* spp. in dogs and cats is being investigated, a thorough diagnostic evaluation to search for other potential causes of vomiting should always be performed before considering *Helicobacter* spp. to be the primary etiologic agent. The purpose of this chapter is to describe the commonly used methods of identifying gastric spiral bacteria in dogs and cats and to review the evidence behind current treatment recommendations. Recommendations for humans with *H. pylori* have been modified by the results of hundreds of clinical studies. Treatment recommendations in dogs and cats no doubt will also change as further studies are performed.

Helicobacter spp. are gram-negative, microaerophilic, motile, curved-to-spiral bacteria with multiple terminal flagella. They contain large quantities of the enzyme urease, which results in the production of ammonia and bicarbonate when in contact with urea. This reaction alters the pH immediately surrounding the bacteria and helps colonize the acidic environment of the stomach.

More than 30 species currently have been identified in humans and animals. In addition to the gastric species, others have also been identified in the intestine and liver. *H. pylori* is the most common gastric species in humans. It has been shown to be a major cause of gastritis and peptic ulcers and to increase the risk of gastric cancer. Infection rates can approach 100% in developing countries and 25% to 60% in developed countries. Infection is usually acquired in childhood and most often persists for life; natural immunity does not clear the infection. Most infected humans remain asymptomatic, but peptic ulcers may occur in 10% of those infected, whereas gastric cancer may develop in 1% to 2% of infected humans. Eradication of *H. pylori* usually results in healing of gastric and duodenal ulcers and complete remission of low-grade gastric mucosa-associated lymphoid tissue (MALT) lymphoma.

Although *H. pylori* has been identified in a research colony of cats, infections in pet dogs and cats with other species of *Helicobacter* is more common. Gastric *Helicobacter* spp. usually found in dogs and cats are larger than *H. pylori* (1.5 to 3 μ m). Initially these large spiral bacteria (4 to 10 μ m) were called *Gastrospirillum hominis* but were later reclassified as *Helicobacter heilmannii*. Other large gastric spiral bacteria such as *Helicobacter felis*, *Helicobacter bizzozeronii*, and *Helicobacter salomonis* occur and are indistinguishable from *H. heilmannii* using rou-

tine light microscopy. Multiple species can also be present within an individual animal. Peptic ulceration associated with gastric *Helicobacter* spp. is rare in dogs and cats, demonstrating a pathophysiologic difference between *H. pylori* and the gastric spiral bacteria commonly found in dogs and cats.

In addition to the role of *Helicobacter* in the pathogenesis of gastritis and chronic vomiting in dogs and cats is the potential for zoonotic transmission. Most evidence indicates zoonotic transmission to be very low, but the potential is real. *H. heilmannii* is a rare cause of gastritis in humans, accounting for approximately 0.1% of cases. An epidemiologic survey of humans with *H. heilmannii* gastritis showed that contact with dogs and cats was a significant risk factor (Meining, Kroher, and Stolte, 1998). In addition, there was an association between *H. heilmannii* gastritis and gastric lymphoma, although this relationship could be coincidental (Stolte et al., 1997). *H. pylori* has also been identified in a research colony of cats, and other studies have identified cat ownership as a risk factor for *H. pylori* infection in humans. Other studies found contact with dogs or cats not to be a risk factor for *H. pylori* infection. Although the potential for zoonotic transmission appears slight, until this issue is conclusively resolved, it seems prudent to identify the presence of gastric *Helicobacter* spp. in dogs and cats during the diagnostic evaluation of chronic vomiting.

DIAGNOSTIC TESTS

Invasive methods of diagnosis of gastric *Helicobacter* infection in humans include bacterial culture, routine microscopic or ultrastructural examination, polymerase chain reaction, or rapid urease testing of gastric mucosal biopsy specimens, usually obtained via endoscopy. Noninvasive methods of diagnosis include urea breath testing, fecal antigen determination, and serology. Although many of these noninvasive tests have been investigated in dogs and cats, they are not routinely available. Presently the clinical diagnosis of gastric *Helicobacter* spp. in dogs and cats requires endoscopic examination or exploratory celiotomy for retrieval of gastric biopsy samples. In our clinic spiral bacteria are identified on gastric biopsy, from brush cytology specimens, or indirectly by a positive rapid urease test of a gastric mucosal sample. Results from a rapid urease test and gastric brush cytology are available much sooner than histopathology. For reasons discussed in the following paragraphs, we consider gastric brush cytology and histologic evaluation of biopsy samples to be the most practical diagnostic tests available for the practicing veterinarian.

Brush Cytology

Gastric brush cytology is the least expensive and most practical diagnostic method with the quickest turnaround time. After completion of an endoscopic examination and collection of biopsy samples from the duodenum and stomach, a brush cytology specimen is collected. A guarded cytology brush is passed through the biopsy channel of the endoscope into the gastric body along the greater curvature. The cytology brush is extended from the sheath and gently rubbed along the mucosa from the

antrum toward the fundus, along the greater curvature. Hemorrhagic areas associated with previous biopsy sites should be avoided. The brush is retracted into the protective sheath and withdrawn from the endoscope. The brush is extended from the sheath, gently rubbed across several glass microscope slides, which are air dried, and stained with a rapid Wright stain (Dip Quick stain, Jorgensen Laboratories Inc.).

The slide is examined under 100× oil immersion. Areas with numerous epithelial cells and large amounts of mucus are examined initially for *Helicobacter* spp. If present, the spiral bacteria are easily seen. They are usually at least as long as the diameter of a red blood cell, and their classic spiral shape is obvious (Fig. 113-1). The number of spiral bacteria can be highly variable, from one every several fields to massive numbers in most fields. We examine at least 10 oil immersion fields on two slides before the specimen is considered negative. Unlike diagnostic tests that involve using a single or several small biopsy samples, brush cytology gathers surface mucus and epithelial cells from a much larger area, increasing the chances for identification of bacteria. Brush cytology was found to be more sensitive than urease testing or histopathologic examination of gastric tissues in identifying gastric *Helicobacter* spp. organisms in dogs and cats (Happonen et al., 1996).

Rapid Urease Test

The rapid urease test detects the presence of bacterial urease, produced by the *Helicobacter* spp., in a gastric biopsy sample. A commercially available test, the CLOtest (Ballard Medical Products, Draper, UT 84020), is used in our clinic (Fig. 113-2). Individual tests cost approximately \$7. An agar gel with urea and a pH indicator, phenol red, is placed within a small plastic well. The tests should be kept refrigerated before use. A routine microbiologic urea slant tube can also be used for this same purpose. An endoscopic biopsy sample obtained from the angularis incisura of the

Fig. 113-1 Gastric brush cytology specimens stained with Dip Quick stain. Large numbers of spiral bacteria are visible. Cellular debris is scattered throughout the photograph. (With permission from Leib and Duncan: *Compend Contin Educ Pract Vet* 27:221, 2005.)

Fig. 113-2 CLOtest Top well is negative. Bottom well has changed color and is positive. (With permission from Leib and Duncan: *Compend Contin Educ Pract Vet* 27:221, 2005.)

stomach is pushed into the gel. The test is maintained at room temperature and examined frequently for a 24-hour period. If bacterial urease is present, urea is hydrolyzed to ammonia, which changes the pH of the gel. The color of the gel turns from yellow to magenta. The rate at which the gel changes color is proportional to the number of *Helicobacter* spp. present in the sample. When large numbers of bacteria are present in the biopsy sample, the rapid urease test quickly changes color, often within 15 to 30 minutes. If the color of the gel has not changed within 24 hours, the test is interpreted as negative.

Occasionally we have observed false-positive tests, perhaps because of contamination of other urease producing pharyngeal or intestinal bacteria, and false-negative tests because of the patchy distribution of bacteria within the stomach or the use of drugs that decrease acid secretion (increase in pH alters the activity of urease). Because of false positives and negatives, the cost of the tests, the turnaround time for results (especially if negative), and the ease and reliability of brush cytology, we find the rapid urease test to be a less valuable diagnostic method.

Histopathologic Identification

Histopathologic identification of *Helicobacter* spp. within gastric biopsy samples, using hematoxylin and eosin (H&E) or special stains, has a specificity of 100% and a sensitivity of greater than 90% in studies in humans. Because of the patchy distribution of organisms within the stomach, examination of samples from multiple gastric locations increases sensitivity. In our clinic samples from the pylorus, angularis incisura, gastric body along the greater curvature, and cardia are examined routinely. Spiral bacteria can be seen within the mucus covering the surface epithelium, the gastric pits, glandular lumen, and the parietal cells (Fig. 113-3). In cats bacteria have been identified submucosally within gastric lymphoid follicles. Spiral bacteria associated with the mucosal surface or within gastric pits are relatively easy to detect with

Fig. 113-3 Photomicrograph of gastric mucosal samples stained with H&E showing spiral bacteria along the mucosal surface (arrows). (With permission from Leib and Duncan: *Compend Contin Educ Pract Vet* 27: 221, 2005.)

routine H&E staining of tissues. However, if the distribution of bacteria favors gastric glands and glandular epithelial cells, bacteria are much more readily detected with a modified Steiner's silver stain. Because of similarities in morphologic characteristics it is not possible to identify specific species using routine histologic staining techniques. Histopathologic evaluation of biopsy samples also allows assessment of inflammation in the stomach and duodenum or identification of neoplasia that may be the cause of the animal's clinical signs.

TREATMENT

Many studies evaluating therapy have been performed in humans with *H. pylori*. The most effective treatment regimens contain two or three antimicrobials combined with a proton pump antagonist given for 1 to 2 weeks.

Multiple antibiotics are used because treatment with a single antibiotic has resulted in eradication rates less than 20%. Studies in humans not only have demonstrated effective regimens but also have evaluated protocols associated with the highest treatment compliance: fewest side effects, the least number of tablets/day, and the shortest duration of therapy. Treatment protocols with eradication rates determined 4 weeks after completion of therapy that are higher than 80% to 90% are considered clinically effective. Reappearance rates after eradication of approximately 1% have been demonstrated, thought mostly to be the result of recrudescence. Successful treatment of bacteria within the gastric lumen is difficult. Antibiotics must penetrate the thick mucus layer within the gastric lumen and be active at an acid pH. The volume of gastric contents is constantly changing during a meal because of acid secretion and gastric emptying. In addition, metronidazole and clarithromycin, and rarely amoxicillin, resistance has been detected in strains of *H. pylori*.

Table 113-1 lists the treatment protocols described in the veterinary literature and used in our hospital. Our current treatment recommendations include either triple therapy with amoxicillin, metronidazole, and bismuth subsalicylate (Pepto Bismol) or dual therapy with clarithromycin and amoxicillin. All treatments are given BID for 2 weeks. Because gastric ulceration does not commonly occur in dogs with gastric spiral bacteria, acid suppression therapy may not be necessary. This may increase treatment compliance by reducing the number of daily medications. A similar benefit may occur with dual therapy, based on preliminary data shown to be as effective as triple therapy in dogs.

We (Leib, Duncan, and Ward, 2007) treated 24 pet dogs diagnosed with gastric *Helicobacter* spp. and chronic vomiting with either amoxicillin, metronidazole, and bismuth subsalicylate (triple therapy) or with triple therapy and famotidine (quadruple therapy). The median duration of vomiting before therapy was 19 weeks, and the median frequency of vomiting was 3.5 episodes per week. The presence of gastric *Helicobacter* spp. was determined by histologic assessment of gastric biopsy specimens

Table 113-1

Treatment Protocols for Gastric *Helicobacter* spp. in Dogs

Protocol	Drugs	Dosage mg/kg	Frequency/day	Duration (days)
Happonen, Linden, and Westermarck, 2000	Amoxicillin	20	BID	10-14
	Metronidazole	10	BID	10-14
	Bismuth subcitrate	6	BID	14-28
Leib, Duncan, and Ward, 2007	Amoxicillin	15	BID	14
	Metronidazole	10	BID	14
	Bismuth subsalicylate	<5 kg-65.5 mg	BID	14
		5-9.9 kg-131 mg		
Leib and Duncan, 2005	Famotidine	10-24.9 kg-262 mg	BID	14
		>25 kg-524 mg		
		0.5		
		15		
Cornetta et al, 1998; Simpson et al., 1999	Clarithromycin	7.5	BID	14
	Amoxicillin	20	BID	14
	Metronidazole	20	BID	14
	Famotidine	0.5	BID	14

obtained before therapy, 4 weeks, and 6 months after completion of therapy. Eradication rates were 70% and 78.5% 4 weeks after therapy for the triple and quadruple therapy respectively. Eradication rates decreased to 44.4% and 41.7% 6 months after therapy for the triple and quadruple therapy groups, respectively. Eight dogs that were negative at 4 weeks were positive at 6 months because of either reinfection or recrudescence of infection.

Both treatments reduced the vomiting frequency compared to the historical vomiting frequency. The median reduction in the frequency of vomiting episodes during the first 4-week period after therapy was 91.8% for triple-therapy dogs and 72% for quadruple-therapy dogs. After completion of therapy, the median reduction in the frequency of vomiting episodes for the entire 6-month period was approximately 86% for both groups. These data suggest that gastric *Helicobacter* spp. caused or contributed to clinical signs in some of the dogs in this study and treatment decreased the incidence of clinical signs.

Because it is often presumed that treatment compliance may decrease as the number of drugs administered increases, omitting acid suppressors in treatment protocols might improve client compliance and treatment success in some cases. Acid suppression may not be necessary in dogs and cats with gastric *Helicobacter* spp. because peptic ulceration is very uncommon when compared to its incidence in humans. However, the use of proton pump antagonists such as omeprazole have been demonstrated to have other potential benefits in humans with *H. pylori*, including bacteriostatic effects in vitro, facilitation of bacterial clearance from the stomach when combined with antibiotics, and inhibition of bacterial urease. Further study of the potential role of acid suppression in dogs and cats with gastric *Helicobacter* spp. is warranted.

The high infection rates 6 months after therapy in the Leib, Duncan, and Ward study (2007) were thought to be caused by initial treatment failure (25%), reinfection from the environment, or recrudescence of infection. High rates of treatment failure and potential recrudescence indicate that more effective treatment regimens should be developed to reach higher than 80% to 90% eradication rates. In our study it was not possible to differentiate between reinfection and recrudescence. It is possible that both treatments were effective initially and reinfection from the environment occurred. Because of canine social habits and the relatively unsanitary nature of the environment in which they live, reinfection after successful eradication therapy seems more likely to occur in dogs than in humans. If further research confirms that reinfection commonly occurs, treatment strategies should include minimizing environmental contamination and exposure, treatment of asymptomatic animals within the household, and possibly periodic retreatment if clinical signs recur.

We are aware of only one other published study that evaluated the effects of triple antimicrobial therapy on gastric *Helicobacter* spp. in pet dogs with upper GI signs (Happonen, Linden, and Westermarck, 2000). Seven of nine dogs that received amoxicillin, metronidazole, and bismuth subcitrate (see Table 113-1) became negative for *Helicobacter* spp. Clinical signs improved in all treated

dogs, including two that remained positive. However, complete resolution of clinical signs required additional therapies. Four of these dogs were reevaluated a mean of 2.5 years after therapy, and all were found to be positive for gastric *Helicobacter* spp. However, these four dogs remained normal or only occasionally had mild clinical signs. The results of this study also suggested that gastric *Helicobacter* spp. contributed to the clinical signs in this group of dogs.

Two studies have evaluated the 2-week treatment of asymptomatic beagles naturally infected with gastric *Helicobacter* spp. with famotidine, amoxicillin, and metronidazole (see Table 113-1) (Cornetta et al., 1998; Simpson et al., 1999). In both reports all dogs were positive for gastric *Helicobacter* spp. 29 days after completion of therapy. It is difficult to compare the results of these two studies with our study because the beagles did not have clinical signs and our study included a third antimicrobial agent, bismuth. Besides its beneficial effects in healing peptic ulcers in humans, bismuth compounds have antimicrobial effects and can suppress but not eliminate *H. pylori* from humans. Bismuth compounds have been shown to decrease the adherence of *H. pylori* from the gastric epithelium, distort bacterial structure by causing vacuolization, and be present both within the cell wall and on the external surface of the bacteria.

Because of the need to identify more effective treatment protocols, we have recently investigated the effectiveness of a dual antibiotic protocol using clarithromycin and amoxicillin. The combination of clarithromycin and amoxicillin with a proton pump antagonist has been very effective in eradicating *H. pylori* in humans with peptic ulceration. Because famotidine did not improve results in our previous study and because of the additional cost of such therapy and the potential for decreased client compliance, a proton pump antagonist was not used. Preliminary results are available for the initial 4 weeks after therapy. The median duration of vomiting was 47 weeks, and the median frequency of vomiting was 1.6 episodes per week. Seventy percent (7 of 10) of dogs became negative 4 weeks after therapy, and the median reduction in the vomiting frequency was 95.5%, although there was considerable variation. More dogs need to be evaluated before conclusions about the effectiveness of this treatment protocol can be made.

In summary, the role of gastric *Helicobacter* spp. as a cause of chronic vomiting in dogs and cats remains speculative. It is our opinion that approximately 50% of dogs with chronic vomiting, chronic gastritis, and *Helicobacter* spp. dramatically improve after successful treatment. It is prudent to determine if gastric spiral bacteria are present in dogs and cats with chronic vomiting. This can be accomplished easily with brush gastric cytology specimens or routine histologic assessment of gastric biopsy samples. If other etiologies of chronic vomiting are not identified, a 2-week treatment protocol for gastric *Helicobacter* spp. is indicated. If clinical signs do not improve after treatment, dietary trials and/or antiinflammatory drugs should be considered. Additional studies will further define the potential pathogenic role of gastric *Helicobacter* spp. in dogs, and more effective treatment recommendations no doubt will emerge.

CHAPTER 114

Gastric Ulceration

RETO NEIGER, *Giessen, Germany*

Ulcers in the stomach form when damage from acid and pepsin overcomes the ability of the mucosa to protect itself and replace damaged cells. Superficial injury of the mucosa results in hemorrhage and erosion; ulcer formation is only seen when the muscular layer is affected. The prevalence of gastric ulcers in dogs or cats is unknown; however, pets are regularly presented with hematemesis, and in these cases some breach of the gastric mucosa is likely.

PHYSIOLOGY

To understand the treatment and prevention of peptic ulcers, it is important to understand gastric secretion and mucosal protection. Acid is produced by the $\text{H}^+\text{-K}^+\text{-ATPase}$ enzymes in parietal cells, which are located in the oxyntic glands. H^+ -ions are pumped into the lumen in exchange for K^+ ; the latter accumulates in the cell and moves down the electrochemical gradient, leaking across the luminal and basolateral cell membranes. Stimulation of the parietal cell occurs via acetylcholine (M_3), gastrin (CCK_B) and/or histamine (H_2) receptors on the basolateral membrane via second messengers (Fig. 114-1). A further hormone, tentatively named *enterooxyntin*, seems to stimulate acid secretion as well (Johnson, 2001). There are several interactions between these secretagogues, and potentiation occurs if two or more stimulants act simultaneously, meaning that the sum of the response exceeds that of each individual response. Histamine is found in enterochromaffin-like (ECL) cells within the lamina

propria of the gastric glands. ECL cells have receptors for gastrin and acetylcholine.

Pepsinogen, produced by chief cells in the gastric mucosa, is converted to pepsin when the pH is below 5.0. Pepsin, which begins the digestion of protein by splitting interior peptide linkages, can itself catalyze the formation of pepsin from pepsinogen. The stimulation of pepsinogen secretion is through vagal activation (acetylcholine), acid-triggered local effects, and in dogs gastrin-induced acid secretion. Secretin, which is produced in the duodenum by secretin cells, also has a pepsinogen-secreting effect, albeit weaker than the other effects.

Three general stimuli or phases are known to initiate gastric secretion: cephalic, gastric, and intestinal. Cephalic stimuli such as tasting, smelling, chewing, and swallowing instigate nerve impulses through vagal efferent stimuli into the stomach. Besides direct activation on the parietal cell, the gastrin (G) cell is stimulated through gastrin-releasing peptide (GRP) or bombesin. In the gastric phase distention of the stomach initiates a vagovagal reflex, meaning that both afferent and efferent impulses are carried through the vagus nerve, which then causes acetylcholine release. Furthermore, peptides and amino acids in the stomach stimulate gastrin release from G cells. Finally, in the intestinal phase digested proteins in the duodenum stimulate acid secretion without increasing serum gastrin levels, potentially through enterooxyntin.

Several mechanisms underlie the remarkable abilities of normal gastroduodenal mucosa to defend itself against

Fig. 114-1 Physiologic mechanism of gastric acid secretion. The parietal cell contains receptors for gastrin, acetylcholine, and histamine. In addition, gastrin and acetylcholine release histamine from the enterochromaffin-like cell (ECL-cell).

injury from acid/pepsin activity in gastric juice and to rapidly repair injury when it does occur. These mechanisms entail three lines of defense: preepithelial, epithelial, and subepithelial (Fig. 114-2). Factors that play a role in maintaining mucosal protection against the ulcerogenic effects of acid and pepsin are mucus; blood flow; bicarbonate secretion; cellular renewal; and chemical factors such as prostaglandins, gastrin, and epidermal growth factor. Surface mucus cells secrete mucoproteins in response to chemical or physical stimuli. This secreted gel entraps alkaline components, neutralizes a certain amount of acid, and prevents pepsin from coming into contact with the mucosa. Prostaglandins play a key role in protecting the gastric mucosa against injury caused by a variety of necrotizing agents. Prostaglandins exert two actions: inhibition of acid secretion and enhancement of mucosal resistance to injury by mechanisms independent of acid secretory inhibition, also called *cytoprotection*.

CAUSES

A variety of causes for peptic ulcers in dogs and cats have been reported. Although nonsteroidal antiinflammatory drugs (NSAIDs) are thought to be the most common cause, the true incidence of gastrointestinal side effects of NSAIDs in dogs is unknown. Only one case of NSAID-induced ulceration has been reported in a cat. NSAIDs are thought to cause gastrointestinal mucosal injury by several mechanisms. Primarily these drugs impair prostaglandin-dependent mucosal protective mechanisms by nonselective inhibition

of two isoforms of cyclooxygenase (COX), COX-1 and COX-2. However, a direct correlation is lacking between the extent of COX inhibition and NSAID-induced gastrointestinal damage (Fig. 114-3). COX-1 inhibition leads to reduced bicarbonate secretion, reduced mucus formation, and vascular actions. Other effects unrelated to prostaglandin synthesis include a “topical” action of NSAIDs on the gastric mucosa, involving mitochondrial injury (“uncoupling”) by a direct toxic action. All commonly used NSAIDs, whether COX-2-specific or not, have been found to cause gastric lesions, although true ulcers with sufficient depth to reach or penetrate the muscularis mucosa seem to be rare. In the largest study of gastric ulcers in dogs, only 4 of 43 cases were thought to have peptic ulcers primarily caused by NSAIDs (Stanton and Bright, 1989). However, close temporal association of various NSAIDs and steroids must be avoided because an increased likelihood of gastric ulceration has been reported (Lascelles et al., 2005).

Corticosteroids alone are hardly ulcerogenic; however, this class of drugs enhances the damaging effect of NSAIDs, hypotension, and other factors causing peptic ulcers. Corticosteroids decrease mucosal cell growth, mucus production, and prostaglandin secretion and enhance gastric acidity. In general, only immunosuppressive doses of prednisolone, when used alone, may result in gastromucosal damage. However, in combination with NSAIDs or concurrent ulcerogenic factors, even antiinflammatory doses can cause *severe* problems; dexamethasone seems to have a higher ulcerogenic property, possibly because of its higher glucocorticoid effect.

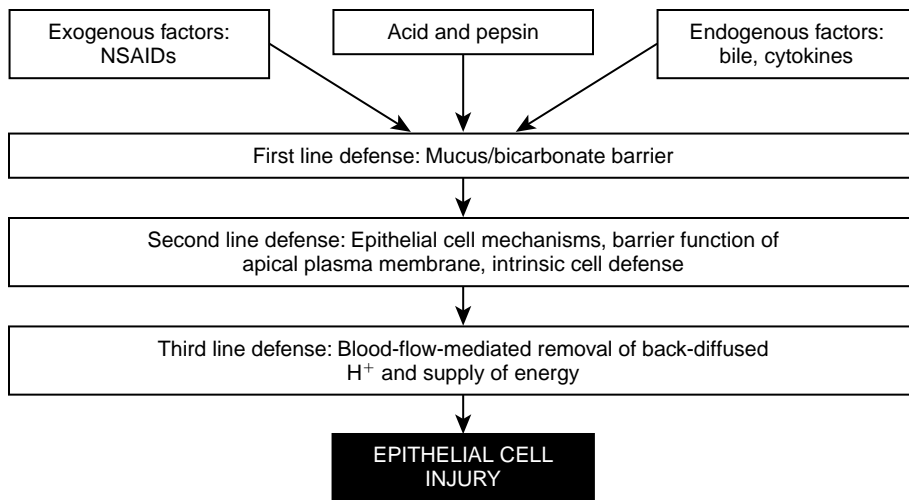

Fig. 114-2 Cascade of mucosal defense. If the three sets of lines of defense mechanisms fail, epithelial cell injury occurs.

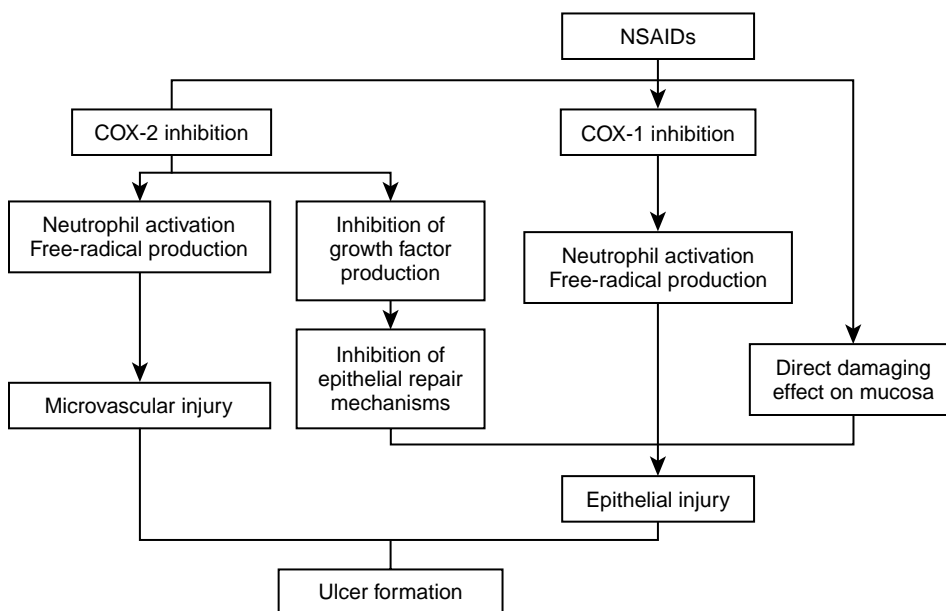

Fig. 114-3 Hypothetic mechanism of NSAID-caused gastric mucosal injury.

One of the most important risk factors for peptic ulceration in dogs is decreased mucosal blood flow caused by hypotension, shock, sepsis, hypovolemia, intervertebral disk disease, or surgery. These factors seem to become even more important if they happen concomitantly or combined with NSAIDs or steroids (Hinton et al., 2002). Less common but still potential risk factors for peptic ulcers are infiltrative gastrointestinal disease, hepatic or renal disease, congestive heart failure, and gastric outflow obstruction.

Large ulcers in the pyloric antral region, often near the incisura, are commonly seen in dogs with gastric tumors. In cats 14 of 33 peptic ulcers were caused by a neoplasia, mostly lymphoma or adenocarcinoma (Liptak et al., 2002). Hyperacidity-induced peptic ulcers caused by a gastrinoma have been described both in dogs and cats; but these tumors are rare, and hyperacidity caused by mast cell tumors rarely develops gastric ulceration.

Although *Helicobacter pylori* is one of the most common causes of peptic ulceration in humans, the status of

gastric *helicobacter*-like organisms causing ulcers or other lesions in the canine and feline stomach is unresolved (see Chapter 113). Gastric ulcers resulting from these spiral organisms have not been reported.

DIAGNOSTIC FEATURES

There are no common signs in animals with peptic ulcers. Vomiting, sometimes with blood, abdominal pain, and nonspecific symptoms such as lethargy and anorexia may be noted. Blood loss into the gastrointestinal tract results in melena, sometimes seen on rectal palpation, and pale mucous membranes if anemia is moderate to severe.

Laboratory tests are nonspecific; however, they are used to rule out other causes of vomiting. Chronic blood loss may result in anemia, sometimes nonregenerative and typical for iron deficiency (hypochromic, microcytic). Biochemistry results may show electrolyte abnormalities as a consequence of profound vomiting. Fecal occult

blood tests are useful only if animals have been on a non-meat diet for at least 3 days before testing and specificity is rather low (Tuffli, Gaschen, and Neiger, 2001).

Survey radiographs are useful in the general workup of the patient; however, they are insensitive to abnormal gastric wall thickness or peptic ulcers. A pneumoperitoneum most often indicates a ruptured viscus such as a perforated gastric ulcer. Contrast radiographs with barium might outline ulceration of the mucosa. The low sensitivity and risk of aspiration pneumonia with barium, the fact that it is a time-consuming procedure, and the problem with a subsequent gastroscopy have made this technique less useful. Ultrasound showing abnormal wall thickness and loss of layers of the mucosa is suggestive of a gastric tumor.

Gastroscopy is the technique of choice to diagnose peptic ulcers. A caveat lies on the characterization of the mucosal damage. The critical characteristic of a true ulcer is that it has sufficient depth to reach or penetrate the muscularis mucosa (i.e., a depth that increases the risk of perforation). However, lesion depth cannot be measured at endoscopy. True ulcers are often confused with the very common and largely trivial erosive lesions found in gastroduodenal mucosa exposed to NSAIDs. That these "endoscopic ulcers" are largely erosive in nature and not true ulcers is borne out by the rarity of clinically relevant bleeding. It is important to inspect the entire stomach and take multiple biopsies from abnormal-looking areas. The rim of an ulcer should be biopsied because the center of the ulcer is usually necrotic tissue.

THERAPY

Treatment of peptic ulcer disease must first address predisposing causes; second, give supportive medications; and last, suppress further damage by suppressing gastric acid secretion. NSAIDs or glucocorticoids should be stopped if possible, and alternative drugs should be used. Tumors are excised surgically (adenocarcinoma, gastrinoma, mast cell tumor) or treated with chemotherapy (lymphoma). Other predisposing factors such as hypotension, stress, and renal or hepatic disease are addressed appropriately.

Fluid replacement for dehydration or a blood transfusion for anemia should be given as needed for gastric ulceration. In a vomiting animal antiemetics are useful to minimize fluid and electrolyte loss and reduce the risk of aspiration pneumonia. If indicated from clinical findings, abdominal ultrasound may be indicated to identify signs of peritonitis related to gastric perforation. Surgical consultation is indicated when perforation is suspected.

The ulcerated mucosa is vulnerable to further damage and mucosal protection with sucralfate (1g/10kg orally [PO] q8h) is indicated. Sucralfate is a sulphated disaccharide-aluminium hydroxide complex that adheres to ulcerated tissue and provides a barrier to acid and pepsin penetration. It also stimulates endogenous prostaglandin synthesis in the gastric mucosa. Since sucralfate is effective at acidic to almost neutral pH, antisecretory drugs can

be used concurrently. However, other orally administered drugs should be given 2 hours apart since sucralfate can affect their absorption.

The cornerstone of peptic ulcer therapy is the reduction of gastric acid secretion; Schwartz's dictum from 1910, "no acid, no ulcer," remains valid today. A variety of drugs are available; the two most commonly prescribed drug classes in veterinary medicine are histamine-2 receptor antagonists (H_2 -RAs) and proton pump inhibitors (PPIs). H_2 -RAs act via competitive inhibition at the histamine receptor on parietal cells (see Fig. 114-1). Several drugs such as cimetidine, ranitidine, nizatidine, and famotidine are available in this group, both in oral and intravenous format, depending on the country. A recent study indicated that ranitidine at the regular dosage (2 mg/kg intravenously [IV] q12h) did not differ from saline in increasing the intragastric pH, whereas famotidine (0.5 mg/kg IV q12h) was significantly more effective than saline (Bersenas et al., 2005). It is the general belief that H_2 -RAs are less effective than PPIs, and it seems that ranitidine might not increase intragastric pH sufficiently in dogs to treat peptic ulcers.

PPIs inhibit the final step of acid secretion, the gastric pump, and thus prevent histamine, acetylcholine, and gastrin-induced acid secretion (see Fig. 114-1). All currently available PPIs are substituted benzimidazoles. A 3- to 5-day lag-phase to achieve maximum acid inhibition has been reported in humans, but this seems not to be the case in dogs. Omeprazole (1 mg/kg PO q24h) and pantoprazole (1 mg/kg IV q24h) were both effective in increasing intragastric pH after 2 days (Bersenas et al., 2005). PPIs are the drug of choice for all hypersecretory states but are also indicated in animals with concurrent risk factors for peptic ulcers and when marked mucosal disruption is seen via endoscopy. It seems that all commercially available PPIs (omeprazole, lansoprazole, esomeprazole, pantoprazole, and rabeprazole) (tenatoprazole launch expected in 2008) are equally effective and safe and have minimal side effects in dogs.

Misoprostol, a synthetic prostaglandin analog, has effects similar to those of endogenous prostaglandins (i.e., stimulation of mucus secretion, increased bicarbonate secretion and gastric mucosal blood flow, and reduction of acid secretion). Because of these properties misoprostol is indicated in preventing NSAID-induced gastric damage. Misoprostol is not indicated when a peptic ulcer is already present since its capacity to reduce gastric acid is far less than that of H_2 -RAs or PPIs. Side effects such as diarrhea and abdominal pain are quite common, and its marked abortifacient effects are a further drawback.

Several other means of decreasing gastric acid are available. Most are not sufficiently effective (e.g., antacids) or are not yet available (gastrin-receptor antagonists, gastrin-releasing peptide receptor antagonists). A class of drugs that might be of future interest is the potassium-competitive acid blocker (P-CAB); P-CABs block the action of the H^+ - K^+ -ATPase by competing with K^+ . Soraprazan and revaprazan are currently under development, but no information in dogs or cats is yet available.

CHAPTER 115

Inflammatory Bowel Disease

ALEXANDER J. GERMAN, *Liverpool, England, United Kingdom*

In companion animal gastroenterology, *inflammatory bowel disease (IBD)* is the term used to describe patients that are affected by persistent or recurrent gastrointestinal (GI) signs and have histopathologic evidence of inflammation in intestinal biopsy material. The condition can only be termed *idiopathic IBD* if no underlying cause for the inflammation can be found. Although there have been recent studies into pathogenesis, diagnosis, and treatment, much controversy remains. A diagnosis of IBD requires detailed investigations to exclude other potential causes of intestinal inflammation; however, it is likely that IBD represents a syndrome comprising a group of disorders with similar characteristics rather than a single disease entity. This chapter briefly reviews the current understanding of this enigmatic condition and then concentrates on current therapeutic practice, highlighting the most recent work in the field.

CLASSIFICATION

IBD is classified according to both the region of the intestine affected and the predominant cell type in the inflammatory infiltrate. Any region of the GI tract may be affected in any combination. The lymphocytic-plasmacytic variety is the most common form reported in both dogs and cats. Eosinophilic inflammation is the second most common type of IBD reported, and there are occasional reports of inflammation with a granulomatous pattern (e.g., regional enteritis). A neutrophilic predominance in the inflammatory infiltrate is rare. However, on many occasions a mixed pattern of cellular infiltrate is described. Despite these different varieties and the importance often placed on histologic classification, little is known of the

significance of such differences in terms of differing etiology, pathogenesis, treatment, and prognosis. Finally certain unique IBD syndromes occur overwhelmingly more often in some breeds; examples include the protein-losing enteropathy (PLE)/protein-losing nephropathy complex in soft-coated wheaten terriers, the immunoproliferative enteropathy of basenjis, IBD in Norwegian lundehunds, and histiocytic ulcerative colitis in boxers.

ETIOPATHOGENESIS

IBD reportedly has an immune-mediated etiology; thus the GI lymphoid tissue (GALT) likely plays a critical part in pathogenesis (German, Hall, and Day, 2003). In brief, the intestinal mucosa has a barrier function (immune exclusion) and controls exposure of antigens to the GALT, which must generate protective immune responses against pathogens while remaining tolerant of harmless environmental antigens such as commensal bacteria and food. IBD develops when the normal decision-making process breaks down, leading to inappropriate immune responses and uncontrolled inflammation. Genetic factors are thought to play a part in disease expression, and examples in human IBD include certain human leukocyte antigen determinants and nucleotide-binding oligomerization domain 2 containing protein (NOD2).

Human Inflammatory Bowel Disease and Animal Models

Much of our understanding of IBD and chronic mucosal inflammation has come from genetically engineered

animal models, which are characterized by a variety of spontaneously arising or induced disruptions of the mucosal barrier, the mucosal immune system, or the endogenous microflora. Critical to the development of inflammation in these models is a breakdown in tolerance to normal luminal antigens (particularly endogenous bacterial species). This loss of tolerance may result from disruption of the mucosal barrier, leading to excessive antigen exposure to the underlying immune system; from dysregulation of normal mucosal immune system function; or from a combination of these processes. The end effect of this tolerance breakdown is uncontrolled inflammation, which is the result of activation of the many effector pathways. The inflammation can then lead to architectural disruption, resulting in adverse effects on function, which depend on the part of the bowel affected.

Companion Animal Inflammatory Bowel Disease Pathogenesis

Although it has been suggested that the pathogenesis of canine IBD is similar to that of the human diseases (ulcerative colitis and Crohn's disease) and mouse models of intestinal inflammation, direct data in support of this supposition are limited. Despite the fact that numerous studies have been performed, many gaps in our understanding remain.

Many studies have used histochemical and immunohistochemical techniques to quantify immune cell populations within the intestinal mucosa with variable results (German, Hall, and Day, 2003). For canine IBD some have shown a decrease in certain lymphocyte populations (total T cells and immunoglobulin [Ig]G⁺ plasma cells); whereas others have shown increases in $\alpha\beta$ -T cells, CD4⁺ T cells, IgG⁺ plasma cells, and macrophage and granulocyte numbers. The confusion is compounded by the finding that in feline IBD, a disease with similar histopathologic changes to the canine form, the only reported difference from control samples was an increase in cells expressing major histocompatibility complex (MHC) class II.

Inconsistent results have also been seen with the studies conducted to date on mucosal cytokine gene expression. First, semiquantitative reverse transcriptase polymerase chain reaction (PCR) studies have suggested increased or decreased gene expression for canine chronic enteropathies. However, more reliable information comes from a recent study using real-time PCR techniques, and this work failed to demonstrate any alteration in cytokine gene expression (Peters et al., 2005). Unfortunately, like its predecessors, this study suffers from the critical flaw that gene expression alone has been assessed and not the functional protein. Nonetheless, even with this limitation in mind, it is odd that such a sensitive and powerful technique as real-time PCR did not detect any alteration in the expression of any cytokine gene. This concern, coupled with the histochemical and immunohistochemical studies that failed to detect immune cell alterations, questions our very understanding of IBD, leading some cynics to ask the question: "if this is IBD, then where is the inflammation?" It may be that the problem lies in the chosen gold standard, namely histopathology, which itself is variable and lacks consensus among pathologists

(see following paragraphs). However, we could actually be dealing with a syndrome in which *inflammation* is present in only a proportion of cases. Perhaps the syndrome would be better known as *idiopathic bowel disease*? Given these limitations to the understanding of companion animal IBD pathogenesis, veterinarians must currently be cautious about their approach to diagnosis and therapy.

An Infectious Etiology for Inflammatory Bowel Disease?

Histiocytic ulcerative colitis is a unique form of IBD, which predominantly affects boxer dogs (also see Chapter 120). The disease is characterized by accumulations of periodic acid-Schiff–positive macrophages, although a mixed inflammatory response with T cells, IgG plasma cells, and macrophages has been noted, together with up-regulation of epithelial MHC class II expression. An infectious etiology has long been hypothesized, but early attempts at disease transmission failed. However, recently the condition has been reported to be sensitive to enrofloxacin, and a recent study has demonstrated that the disease is associated with selective intramucosal colonization by *Escherichia coli* strains (Simpson et al., 2006). These strains have an adherent and invasive phenotype and similarities to similar organisms isolated from the mucosa of Crohn's disease patients.

DIAGNOSIS OF INFLAMMATORY BOWEL DISEASE

A detailed investigative workup usually is required for the IBD case. Given that IBD is largely diagnosed on histopathologic criteria, intestinal biopsy is an essential step in diagnosis. Often a staged approach is recommended that involves a combination of laboratory tests (blood tests, urinalysis, fecal analyses) and diagnostic imaging in addition to histopathologic assessment of intestinal tissue samples. Furthermore, given the current controversies over definition and diagnosis of IBD, well-conducted therapeutic trials have now become an important diagnostic tool. Thus not only can the condition be better defined (food-responsive, antibacterial-responsive), but a superior treatment plan is also put in place in which only those therapies truly required are used.

Recent Advances in Laboratory Testing

A recent innovation in assessment of intestinal protein loss is measurement of fecal α_1 -proteinase inhibitor concentrations. This test correlates well with the gold standard for intestinal protein loss. Preliminary work has suggested that it is valuable for the diagnosis of PLE, and it may prove to be a more sensitive marker than serum albumin concentrations for the detection of early disease.

Although measurement of serum cobalamin concentrations is not novel, this test remains of critical importance when assessing cases of chronic GI disease. Deficiencies in either of these B vitamins are not pathognomonic for the presence of any particular GI condition, but they alert the clinician to the presence of intestinal malabsorption. Cobalamin deficiency may have systemic metabolic consequences, and response to specific therapy may be

suboptimal if it remains unresolved. A recent study has also demonstrated that this is a common complication of feline GI disorders (Simpson et al., 2001).

Diagnostic Imaging

Although both radiographic and ultrasonographic studies can be used in investigation of patients with GI signs, ultrasonography has become the preferred imaging tool. It can be used to assess all abdominal organs and help eliminate the possibility of disease in other organs. The whole of the intestinal tract can also be examined directly, and wall thickness can be measured. It was suggested previously that increased wall thickness occurs in canine IBD, but recent work has suggested this measurement to be of no significant value in IBD diagnosis. Instead the power of ultrasonography is more for its ability to document focal intestinal disease and enable targeted cytologic analysis. In the future, Doppler may prove to be a useful tool for investigation of intestinal disease since a recent work has suggested that it may be useful to aid in the diagnosis of food sensitivity disorders (Kircher et al., 2004).

Intestinal Biopsy

Intestinal biopsy is essential to prove the presence of intestinal inflammation and confirm a diagnosis of IBD. Endoscopic biopsy is the simplest and least invasive method of specimen collection; limitations include small sample size, superficial samples, and limited sampling sites (stomach, proximal small intestine (SI), distal ileum [occasionally], and colon). In some cases exploratory celiotomy and full-thickness biopsy are necessary, although this procedure is more invasive and wound healing can be problematic if severe hypoproteinemia is present and corticosteroids need to be given urgently. However, it may be more suitable for cats, given the tendency for concurrent hepatic and pancreatic involvement and the small size of endoscopic biopsies achievable in this species.

Although the histopathologic assessment of intestinal biopsy material remains the gold standard for diagnosis of many intestinal diseases, it has marked limitations. The major problem is the poor agreement among pathologists (Willard et al., 2002). In this study overall agreement among pathologists was poor, and some even made a diagnosis of lymphoma after assessing tissues from healthy dogs. Histopathologic scoring schemes and standardized criteria have been suggested as a means of improving agreement, but marked variability in interpretation still exists. A World Small Animal Veterinary Association-sponsored Gastrointestinal Standardization Group has been established to try to resolve these inconsistencies, and it is hoped that a reliable grading scheme will be developed in the near future.

Ultimately the primary clinician must interpret histopathology results cautiously and try to relate them to the clinical presentation. Results should be questioned if the histopathologic diagnosis does not fit the clinical picture or the response to apparently appropriate therapy is poor. In some cases repeat biopsy (e.g., by exploratory celiotomy) may be required. Alternative methods of assessing biopsy tissue include immunohistochemical or

flow cytometric characterization of mucosal immune cell populations and assessment of T-cell clonality. However, although such techniques may be useful in the diagnosis of alimentary lymphoma, they have not yet been shown to be of use in the diagnosis of IBD.

Two more recent markers with potential use in IBD are mucosal perinuclear antineutrophilic cytoplasmic antibody (pANCA) and lamina propria lymphocyte P-glycoprotein expression. High pretreatment pANCA expression has recently been shown to correlate with cases that respond principally to dietary therapy rather than those that ultimately respond to steroids (Luckschander et al., 2006). Thus assessment of pANCA expression pretreatment could help predict the most appropriate therapy for a particular case. P-glycoprotein is a transmembrane protein functioning as a drug-efflux pump in the intestinal epithelium. In human IBD cases high lymphocyte P-glycoprotein expression is seen in patients who fail to respond to treatment with steroids. Recent work in canine IBD demonstrated that low pretreatment mucosal lymphocyte P-glycoprotein expression correlated with a favorable response to treatment, suggesting that it may be a useful predictor of prognosis (Allenspach et al., 2006). However, the main limitation of this assay is the necessity for repeat endoscopy to monitor cases, given that many owners may be reluctant to allow their pet to undergo such procedures.

Treatment As a Diagnostic Tool

After the diagnostic investigations have been performed, a frequent mistake is to assume that the work of the clinician is done. In many cases clinicians can instigate an organized therapeutic plan that helps to confirm the diagnosis (based on the treatment to which the case responds) and tailor therapy to the individual case. Unless the animal is debilitated, I prefer to instigate single therapeutic modalities sequentially, and the owner is asked to record precisely in an event diary the frequency and nature of clinical signs. The clinician should review the diary on a regular basis to ascertain whether each treatment has led to a genuine improvement in clinical signs. My favored order of treatment trials is anthelmintic/antiparasitic medication (e.g., fenbendazole, 50 mg/kg q24h orally [PO] for 3 to 5 days), followed by dietary modification (preferably with an antigen-limited or hydrolyzed protein diet) for 3 to 4 weeks, followed by a 3- to 4-week antibacterial trial (usually tylosin, 10 mg/kg q8h PO, or metronidazole, 10 mg/kg q12h PO), and finally trial immunosuppressive therapy (initially prednisolone, 1 mg/kg q12h PO). Often partial responses to single agents are noted; in such cases the genuine need for multimodality therapy can be justified. The treatment trial approach is labor intensive but is the best way of achieving successful resolution of the clinical signs. Clients appreciate the interest shown by the clinician and are more accepting of the advice than when communication is poor following diagnosis.

MONITORING PROGRESSION OF INFLAMMATORY BOWEL DISEASE

In all species IBD is a condition that is most commonly controlled rather than cured with therapy. Currently the

preferred approach to monitoring outcome is assessing for resolution of clinical signs. In humans activity indices are used to quantify IBD disease severity, aiding the assessment of the response to treatment and the prognosis and allowing comparisons among published studies in the literature. Recently an activity index has been suggested for canine IBD. Its use in the clinical setting provides a more objective measure of therapeutic response. However, clinicians must understand that increases in canine IBD activity index (CIBDAI) simply suggest an increase in severity of GI signs and that high values do not confirm the diagnosis of IBD. This was demonstrated in a recent paper in which increased CIBDAIs were seen in dogs with food-responsive conditions and values decreased on successful treatment (Spichiger et al., 2006). Thus perhaps CIBDAI should instead be known as chronic GI disease activity index.

Recent research has investigated novel methods of monitoring therapy in IBD; these include noninvasive (e.g., acute-phase proteins, insulin-like growth factor-1 [IGF-1]) and invasive (e.g., repeat histopathologic examination, P-glycoprotein) techniques. For example, C-reactive protein is an acute-phase protein that is elevated in dogs with IBD and reduces on resolution of therapy, correlating with a decrease in CIBDAI (Jergens et al., 2003). Plasma IGF-1 has recently been assessed in canine IBD and been shown to increase on successful therapy (Spichiger et al., 2006). Although such methods may prove to be useful for monitoring in the future, the main current limitation is the lack of commercial availability of the assays.

TREATMENT

Despite the fact that much has been written on therapy for companion animal IBD, most is opinion, and there remains little objective evidence of efficacy for any modality. Therefore this review focuses on my preferred approach, together with evidence that is available from peer-reviewed publications.

Approach to Therapy

The fact that IBD is usually controlled rather than cured is highlighted by a number of cases that have shown that mucosal inflammation remains despite resolution of clinical signs. In addition, most cases respond to combinations of therapy rather than single agents. The therapy used includes dietary modification, antibacterials, and immunosuppressive drugs. As described previously ("Treatment as a Diagnostic Tool"), I use a staged approach to therapy, except in seriously ill patients in which immediate intervention with immunosuppressive medication may be essential.

Dietary Management of IBD

Most clinicians would agree that dietary management is a key component in the successful treatment strategy for IBD cases, and in support of this dietary modification has recently been shown to play a critical part in long-term therapy for cats with chronic GI disease (Guilford et al., 2001). The main options for dietary management include switching to a highly digestible diet, an exclusion diet, and/or a diet high in fiber.

High digestibility ensures that components can be assimilated readily in the face of suboptimal digestive function. Efficient absorption also minimizes the substrate that is available to intestinal bacteria or for commanding an osmotic potential. Protein should be of high biologic value. Gluten is perceived to be a common food allergen, largely because of its known association with gluten-sensitive enteropathy in Irish setters. As a result, most formulated diets are now gluten free. However, although undoubtedly responsible for some adverse reactions to food, there is no evidence that gluten is any more antigenic than other commonly fed proteins. Fat restriction traditionally was recommended because of concerns over malabsorption, meaning that unassimilated fatty acids could be available for hydroxylation, thus stimulating electrolyte secretion. However, the need for fat restriction has recently been challenged since most cases can tolerate a higher dietary fat content and fat restriction may exacerbate existing weight loss. Supplementation with ω -3 fatty acids may also be of benefit in treating inflammatory diseases, although as yet there is no direct evidence confirming efficacy.

Exclusion diets are used when an adverse reaction to food is suspected; they are covered in more detail elsewhere. Most commercial exclusion diets are also highly digestible, enabling clinicians to choose the same diet for both purposes. The main recent advance in this field has been the advent of hydrolyzed protein diets, in which a native chicken or soy protein has undergone chemical or enzymatic treatment, producing low-molecular weight protein derivatives. In theory such diets should be less antigenic, and recent work has demonstrated reduced *in vitro* antigenicity compared with the native molecule. Their other main benefit is the improved digestibility of the protein components, which may be superior to traditional single-source protein-exclusion diets. Thus they are now the exclusion diet of choice for many clinicians, and recent clinical trials in both dogs and cats have been encouraging.

High-fiber diets are used most commonly in cases presenting predominantly with large intestinal signs. The clinician can either choose a purpose-formulated commercial diet or add a fiber supplement (e.g., Ispaghula husk) to the existing diet. Different fiber sources have different physiologic properties. Dietary fibers with a low solubility include cellulose and have their effect by increasing the bulk in the intestine, binding nonabsorbed fluid, and helping to regulate intestinal motility. Fibers with higher solubility include beet pulp, pectins from carrots or fruits, and gumlike fiber. These fiber sources can be easily fermented by intestinal bacteria, and the short-chain fatty acids (e.g., butyric acid) that are released can be partly used by the colonic mucosa. Further the addition of fermentable dietary fiber reduces the concentrations of some bacteria that are potentially harmful and increases the concentrations of some bacteria that are regarded as being beneficial. Thus a mix of insoluble and soluble fiber is usually chosen; either a purpose-formulated commercial ration can be used, or a fiber supplement can be added to the existing diet.

Whichever type of diet is chosen, it must be palatable and should be introduced in gradually increasing amounts over 4 to 7 days. It is best to feed the chosen

diet exclusively in small, frequent meals (e.g., four to five per day). Finally, although enteral nutrition is usually preferred, parenteral nutrition may be beneficial in a case of severe, debilitating IBD.

Antibacterial Therapy

The use of antimicrobials in IBD can be justified in part by the potential to treat any undiagnosed enteropathogens and in part by the fact that it is bacterial antigens that are thought to drive the pathogenetic pathways. Currently metronidazole (10mg/kg q12h PO) is the preferred antibacterial for most forms of IBD in small animals, and it has long been suggested to have immunomodulatory properties in addition to an antimicrobial action. Tylosin (10mg/kg q8h PO) may also have immunomodulatory effects and may have some efficacy in canine IBD.

Although few studies demonstrate the efficacy of both of these drugs in companion animal IBD, a recent study in a rat model of IBD (colitis induced by 2,4,6-trinitrobenzene sulfonic acid) has suggested that tylosin is effective in decreasing inflammation (Menozzi et al., 2005). This work is particularly interesting in light of the recent report of a series of dogs with diarrhea that responded to tylosin therapy (see Chapter 116). However, the relationship between this condition and the IBD syndrome is not well understood. Finally, there are recent reports that histiocytic ulcerative colitis of boxers is responsive to enrofloxacin, supporting the hypothesis that this particular form of IBD is the consequence of an infection with a specific organism (see earlier discussion).

Antiinflammatory and Immunosuppressive Therapy

The mainstay of immunosuppressive therapy is prednisolone or prednisone (both 1 mg/kg q12h, PO initially, then tapering) with or without azathioprine in dogs (2mg/kg q24h PO initially, then tapering) or chlorambucil (2 to 6mg/m² q24h PO) in cats. However, controlled clinical trials on the use of these medications are lacking. A recent study in dogs has suggested that CIBDAI decreases on successful treatment with steroids (Spichiger et al., 2006), although neither mucosal permeability nor histopathologic abnormalities change significantly. This further supports the supposition that the condition is controlled rather than cured with such therapy. Hematologic parameters should be monitored regularly if azathioprine or chlorambucil is used. If cases respond, the medication can be tapered gradually, starting with the steroid, to an every-48-hour dosing regimen.

Budesonide is a glucocorticoid medication with high first-pass metabolism, and an enteric-coated formulation of this drug has been successful in maintaining remission in human IBD. A preliminary study showed apparent efficacy in dogs and cats, but limited information on the use of this drug is available. However, hypothalamic-pituitary-adrenal suppression and development of a steroid hepatopathy have been demonstrated in dogs. The optimal dosage has not yet been determined, although anecdotally a dosage of 1 mg/m² every 24 hours orally has been recommended. Sulfasalazine (and related drugs) are

often used in dogs when IBD is limited to the large intestine. Side effects include keratoconjunctivitis sicca; therefore tear production should be monitored regularly.

A recent uncontrolled study has shown that cyclosporin (5 mg/kg q24h PO) may be effective in IBD that is refractory to steroid therapy (Allenspach et al., 2006). Cases responded to therapy based on improvement noted by CIBDAI. Biopsies taken after cyclosporin therapy showed a decrease in T cell numbers but no change in histopathology scores. A single case study recently reported response of severe IBD with concurrent hypoproteinemia and lymphangiectasia, to methotrexate after a combination of prednisolone and cyclosporin was ineffective (Yuki et al., 2006). This observation should be confirmed with larger case series and preferably evidence-based medicine before routine use of this drug can be recommended.

Treatment of Patients With Severe Protein-Losing Enteropathy

PLE is a recognized complication in a subset of IBD cases (Chapter 118), and the presence of low serum albumin concentrations (suggesting severe PLE) has been shown to be a poor prognostic marker in IBD. Patients with albumin concentrations of 1.5g/dl (or below) are at risk of developing ascites, pleural effusion, and subcutaneous edema. They may also be at risk of complications associated with intestinal biopsy by celiotomy; plasma transfusion, human albumin infusion, or synthetic colloid (e.g., hydroxyl-ethyl starch) may be indicated during the perioperative period. Further, I usually hospitalize such cases for the initial treatment period, enabling cage rest (which may assist with the clearance of ascites fluid), and allowing use of glucocorticoids by the parenteral route (ideally using a prednisolone preparation designed for intramuscular injection). This approach is based on the potential for concurrent malabsorption, meaning that oral preparations may not be adequately absorbed. I favor an intramuscular preparation of prednisolone (Deltastab, Sovereign Medical; 2 mg/kg, q24h intramuscularly) and use both serum albumin concentrations and clinical signs to assess response. Once albumin concentrations begin to increase, oral glucocorticoid medications can be substituted; assuming that albumin concentrations continue to climb, the patient can be discharged from the hospital. Finally diuretics may be required for the management of effusions, and combinations of diuretics are preferred (e.g., furosemide and spironolactone) with monitoring of serum electrolytes and renal function.

Adjunctive Therapy

Hypocobalaminemia is common in both dogs and cats with IBD and should be corrected with parenteral supplementation if present. I use a dosage of 20mcg/kg every 7 days subcutaneously for 4 weeks and then the same dosage every 28 days for a further 3 months. Reassessment of serum cobalamin concentration verifies the efficacy of therapy. Thromboembolism is a feature of some patients with PLE, and prophylactic low-dose aspirin has been advocated. A small cases series in canine IBD suggested an association with iron deficiency anemia and required iron supplementation to correct.

Probiotics have been suggested to be beneficial for human IBD, although no truly objective data (e.g., double-blind placebo-controlled trials) exist despite promising initial reports. More work is required before probiotic use becomes commonplace in companion animal IBD therapy.

PROGNOSIS

Many clinicians have the impression that treatment of companion animal IBD has a high success rate, but in published reports the actual response rate is variable. A recent retrospective paper suggested that only 26% of cases progress to complete remission, intermittent signs remain in approximately half of cases, 4% are completely uncontrolled, and 13% are euthanized because of poor response (Craven et al., 2004). This suggests that prognosis is guarded and quality of life of IBD patients can be poor. The main negative prognostic sign identified was that of hypoalbuminemia.

CHAPTER 116

Tylosin-Responsive Diarrhea

ELIAS WESTERMARCK, *Helsinki, Finland*

Antibiotic treatment often leads to resolution of clinical gastrointestinal (GI) signs, and thus the term *antibiotic-responsive diarrhea* was coined for these cases. Recently trials have been published in which the antibiotic tylosin proved to be particularly effective in treating dogs with chronic or intermittent diarrhea, with the effect of tylosin differing from that of other antibiotics; thus it is referred to as tylosin-responsive diarrhea (TRD).

CLINICAL PHARMACOLOGY

Tylosin is a macrolide, bacteriostatic antibiotic that has activity against most gram-positive and gram-negative cocci, gram-positive rods, and *Mycoplasma*. However, the

gram-negative bacteria *Escherichia coli* and *Salmonella* spp. are intrinsically tylosin resistant. Tylosin is used only in veterinary medicine, and the most common indications are for treating pigs with diarrhea or poultry with chronic respiratory diseases. Tylosin has also been used as a feed additive in food animal production, and it has been shown to increase weight gain and feed efficiency, especially in pigs. There is debate into the mechanisms underlying tylosin-mediated growth enhancement.

Tylosin is used in a powder form for pigs and poultry. For small animals tylosin powder is usually reconstituted in capsules or mixed with the food for administration. In some European countries tylosin is also available in tablet form, which facilitates its use in dogs.

THERAPEUTIC USE

My experience with tylosin was first derived from studies in dogs having exocrine pancreatic insufficiency (EPI) and continued diarrhea following appropriate enzyme therapy. These studies found that tylosin had a favorable effect as a supportive therapy for dogs with EPI and diarrhea.

In recent years in Finland tylosin has become the most frequent antibiotic used in the treatment of nonspecific intermittent or chronic diarrhea in dogs. Anecdotal reports from veterinarians and dog owners reveal that many dogs with diarrhea respond quickly to tylosin treatment, generally within a few days of initiation of therapy. When tylosin is discontinued, the diarrhea often reappears within a matter of weeks or months. Some of these dogs require ongoing treatment for very long periods of time. It was also observed that the tylosin effect in controlling diarrhea signs does not appear to diminish with time and the need for an increased dosage is not required. No apparent tylosin-associated adverse effects have been reported.

My clinical experience finds that TRD affects dogs of all breeds and ages, but is most often observed in middle-aged, large-breed dogs. Signs often begin as intermittent diarrhea that becomes progressively more frequent and often persistent. Abnormal loose fecal consistency is the predominant sign. The majority of the owners describe their dogs' feces as watery and or of mucoid consistency, suggesting that TRD involves both small- and large-bowel diarrhea. Increased frequency of borborygmus and flatulence typically are also described, and vomiting is reported occasionally during the diarrheal outbreaks.

Diagnostic evaluation of TRD cases have failed to identify an underlying etiology. Routine blood parameters, fecal examinations, and diagnostic imaging studies are usually normal. When intestinal biopsies are obtained, the histologic findings are considered either to be normal or to have only mild inflammatory changes.

CLINICAL STUDIES USING TYLOSIN FOR CHRONIC DIARRHEA

Only a few studies treating diarrhea in dogs with tylosin have been published. Van Kruiningen (1976) reported over 30 years ago that tylosin was effective in the treatment of unspecific canine diarrhea. Recently our study group performed two prospective clinical trials to obtain more information on TRD (Westermarck E et al., 2005). The first study consisted of 14 adult client-owned dogs of 12 different breeds. Each dog's diet remained unchanged throughout the study. All dogs had chronic or intermittent diarrheal signs for a period of longer than 1 year. All dogs previously had been treated successfully with tylosin for at least 6 months. Tylosin had been discontinued at least twice, but the diarrhea had always recurred. These dogs were then considered to have TRD. When the study commenced, all dogs had been on tylosin for at least 1 month and were healthy and free of diarrhea. Tylosin was then discontinued, and the dogs were monitored for a period of up to 1 month to determine whether signs of diarrhea would reappear. Diarrhea reappeared in 12 of

14 dogs (85.7%) within 30 days. Tylosin, prednisone, or a probiotic treatment trial was initiated when diarrhea was present. Tylosin resulted in resolution of diarrhea in all dogs within 3 days of initiation of therapy, with most resolving within 24 hours. In contrast, prednisone did not completely resolve diarrheal signs, and the probiotic *Lactobacillus rhamnosus* GG did not prevent the relapse of diarrhea in any of the dogs.

In a second study seven beagles with chronic diarrhea for a duration of at least 1 month were identified from an experimental dog colony. Treatment trials of antibiotics, prednisone, and diet were used. Tylosin was administered for 10 days, and during that time the feces became significantly firmer, although they remained unacceptably loose. When the treatment was discontinued, diarrhea reappeared within 3 weeks. Next treatment trials with other antibiotics (metronidazole, trimethoprim-sulfadiazine, or doxycycline) and prednisone had almost no effect on fecal consistency in these dogs. The diet was then changed for a 10-day period from a highly digestible moist pet food to a dry food developed for normal adult dogs. The feces again became significantly firmer, although the fecal consistency remained loose in some dogs. The dry food feeding period was then extended to 3 months, and the fecal consistency continued to fluctuate from ideal to diarrhea. Since the consistency was not satisfactory on diet alone, tylosin was added to the therapy for 10 days. The fecal consistency became normal and remained so throughout the entire 3-month follow-up time of this study. The study demonstrated that, in this group of experimental dogs having chronic diarrhea, the fecal consistency became significantly firmer using tylosin in conjunction with dietary modification. Neither treatment alone was sufficient to obtain ideal fecal consistency; but, when the dogs were treated simultaneously with both regimens, ideal fecal consistency was achieved and maintained. The study suggests that tylosin and feeding regimens had a synergic effect.

PATHOPHYSIOLOGY

The etiology of TRD remains obscure. Since tylosin is an antimicrobial agent, it has been speculated that some pathogenic bacteria likely are responsible for the diarrheal signs. Based on negative fecal culture results and enzyme-linked immunosorbent assay testing for clostridial enterotoxin, we have excluded such common enteropathogenic bacteria as *Clostridium perfringens*, *Clostridium difficile*, *Salmonella* spp., *Campylobacter* spp., and *Yersinia* spp. as causative factors for the diarrheal signs occurring in TRD. Less well-defined species causing diarrhea in dogs such as *Plesiomonas shigelloides*, *Lawsonia intracellularis*, and *Brachyspira* spp. were also excluded.

Our ongoing studies have revealed that administration of tylosin leads to significant but transient changes in the composition of the small intestinal microflora. The results support the hypothesis that tylosin promotes the growth of beneficial commensal bacteria while suppressing deleterious bacteria.

In addition to antibacterial properties, tylosin may also possess antiinflammatory properties, contributing to its effectiveness in treating canine diarrhea. The mode of

action is most likely different from the immunomodulatory effects of prednisone because prednisone treatment did not completely resolve diarrheal signs in the dogs that responded to tylosin.

DIAGNOSTIC PROTOCOL FOR CHRONIC DIARRHEA

The diagnostic protocol used for dogs with chronic diarrhea by the Faculty of Veterinary Medicine at the University of Helsinki is represented in Fig. 116-1. In patients with chronic diarrhea, every effort should be made to achieve a diagnosis to enable a specific therapy. Unfortunately this is not always possible, in which case empiric therapeutic trials are used in the workup of these patients. There are conflicting opinions about how long an empiric therapy should be attempted. We recommend 10 days if a dog has chronic diarrhea or if the interval between intermittent diarrheal episodes is only a few days. If signs of diarrhea disappear or resolve during this period, the treatment should be continued another 2 to 6 weeks. When the interval between episodes of intermittent diarrhea is long (i.e., more than 1 week), the length of the empiric treatment period should be prolonged. The workup protocol displayed in Figure 116-1 for patients with chronic or intermittent diarrhea is applicable for most veterinary

practices. It is also useful regardless of whether the clinical signs are typical of large or small intestinal disease.

The initial evaluation (A) comprises obtaining a thorough case history, conducting a physical examination, and taking the basic laboratory tests, including a complete blood count, a serum chemistry profile, fecal evaluation for parasites, and measurement of serum concentrations of trypsin-like immunoreactivity. According to the initial evaluation, the patients are then divided into one of two groups. The first group includes patients in which abnormal findings are identified (Group B), whereas the second group has no obvious abnormalities other than diarrhea (Group C).

Patients in group B identified with obvious abnormalities of systemic disorders (B1a) such as hepatic failure, renal failure, hypoadrenocorticism, or EPI (B1b) require specific therapy. Animals having hypoproteinemia (B1c), melena and/or anemia (B1d), or abnormal palpation findings (B1e) require advanced diagnostics (D), including imaging studies, endoscopy, and/or intestinal biopsy. Most often these animals have inflammatory bowel disease, lymphangiectasia, or GI neoplasia.

Dogs with diarrhea but no identified abnormalities (C) on the initial evaluation are first treated orally with fenbendazole 50mg/kg for 3 days (C1) to rule out endoparasites as the causative factor for GI signs. When endoparasites have been ruled out, adverse food reactions (C2)

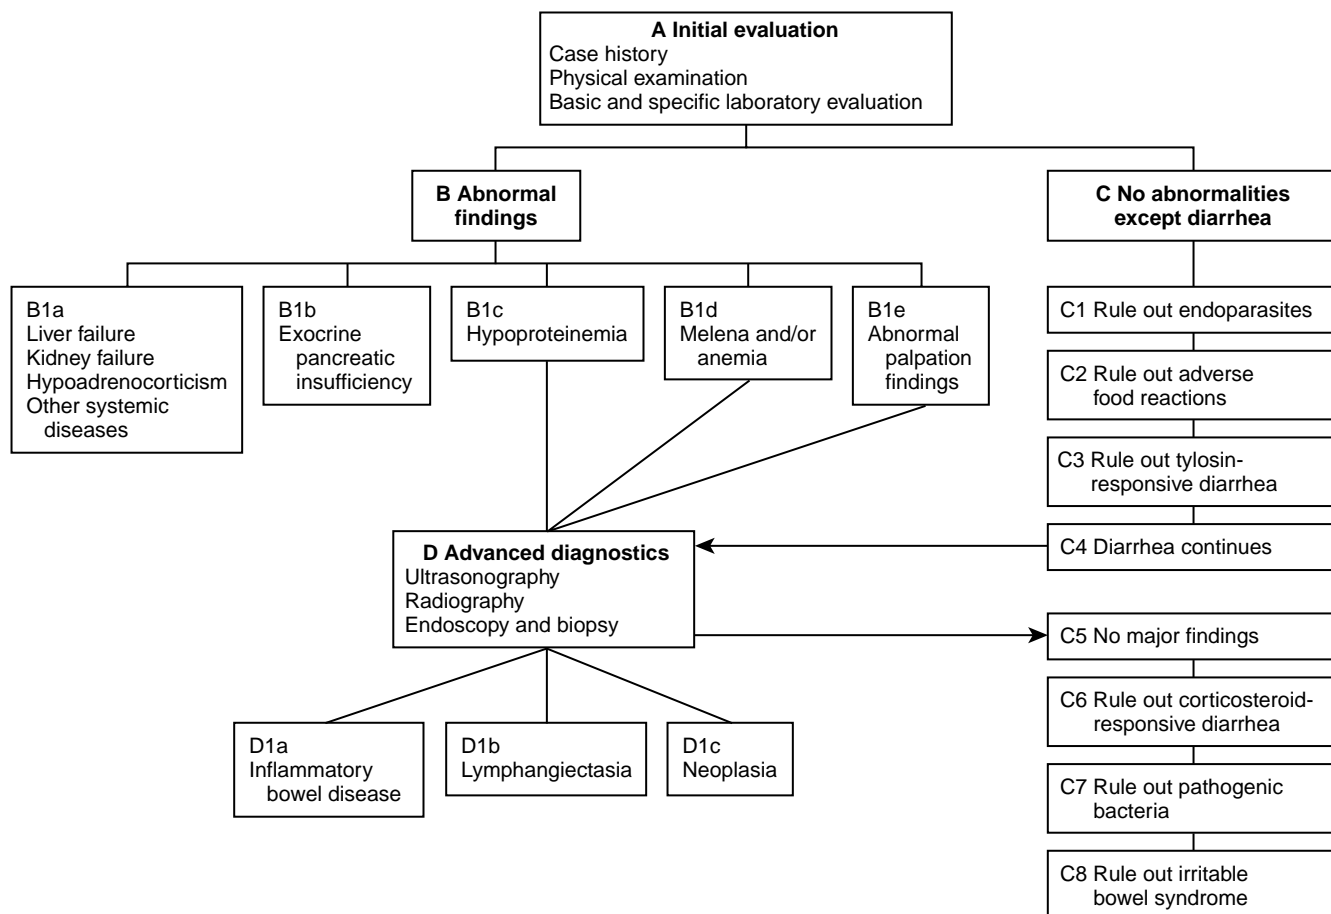

Fig. 116-1 Diagnostic approach to dogs presenting with chronic diarrhea at the Veterinary School in Helsinki, Finland.

should be investigated. Food is probably the most common cause of diarrhea, and adverse food reactions should always be excluded before empiric treatment trials with different drugs are initiated. Opinions vary widely on the type of diets used for a dietary treatment trial (see Section VI on the Evolve site). Unfortunately current recommendations are largely based on anecdotal evidence rather than on controlled trials. The most common recommendation is to use a diet with novel protein and carbohydrate sources, with the protein restricted to a single animal source.

If modifying the feeding regimen fails to produce a satisfactory fecal consistency, the next step is to treat the dog with tylosin 25 mg/kg of body weight every 24 hours (C3). Dogs responding to tylosin treatment usually do so within 3 to 5 days, and the stool remains normal as long as treatment continues. In many TRD cases the diarrhea reappears within weeks on discontinuation of treatment. If diarrheal signs reappear, further dietary trials should once again be initiated to make sure that an adverse food reaction is not involved in the etiology of the signs. If diarrheal signs continue, tylosin treatment is reinitiated. I have treated TRD in some dogs for years. The dose of tylosin for long-term use should be tapered to the lowest possible dose that controls the clinical signs. Many dogs may need only half of the recommended dose to be diarrhea

free. Although no adverse effects during tylosin treatment have been observed, efforts should be made to reduce or discontinue the use of tylosin if possible. Recently studies that I conducted identified that tylosin causes wide resistance to intestinal antibiotics (unpublished results).

Certain probiotic lactic acid bacteria (LAB) have been shown to be effective in the prevention and treatment of a variety of diarrheal disorders in humans and in experimental mouse models. Possibly a probiotic LAB can be used instead of tylosin to treat or prevent chronic diarrhea in dogs with TRD.

Dogs not responding positively to dietary modification or tylosin treatment require advanced diagnostic studies (D). The workup is continued and further diagnostic considerations as displayed in Figure 116-1.

CHAPTER 117

Tritrichomonas

JODY L. GOOKIN, *Raleigh, North Carolina*

Trichomonads are flagellated protozoans characterized by an undulating membrane that courses along the length of a pear-shaped body. They are similar in size to *Giardia* spp. and obligate parasites of warm, moist, anaerobic areas within the gastrointestinal or genitourinary tract of their hosts. Trichomonads do not form cysts, they reproduce by binary fission, and they are transmitted directly from host to host in the form of trophozoites. Pathogenic and nonpathogenic species of trichomonads can be found in animals. *Pentatrichomonas hominis* inhabits the large intestine of a number of mammalian hosts and is considered to be a commensal, whereas *Tritrichomonas foetus* is recognized as an important venereal pathogen of naturally bred cattle. *T. foetus* was first identified as a cause of chronic large bowel diarrhea in cats in 2003; the duration of its existence in cats before that time is unknown (Levy et al., 2003). In cats *T. foetus* colonizes the distal ileum and

colon, resulting in lymphoplasmacytic and neutrophilic colitis and chronic foul-smelling diarrhea. The prevalence of *T. foetus* infection is high among densely housed cats, with 31% of 117 cats from 89 catteries sampled were positive at an international cat show (Gookin et al., 2004).

SIGNALMENT AND CLINICAL FINDINGS

Generally cats with diarrhea and *T. foetus* infection are young, but asymptomatic infection in older cats may also be common. Cats originating from a cattery (e.g., pure-bred) or shelter appear to be at increased risk for infection because of a history of dense housing. A true breed predisposition has not been shown (Gookin et al., 2004). Clinical signs are characterized by large bowel diarrhea occasionally containing fresh blood and mucus. Diarrhea is semiformal to cowpie in consistency and malodorous.

In very young cats and with poor housing conditions, the anus may appear inflamed and painful; involuntary dribbling of feces or rectal prolapse may be present. In general, cats maintain good health and normal appetite and body condition. Consistency of the diarrhea waxes and wanes and typically improves during antimicrobial treatment but quickly resumes when treatment is discontinued (Gookin et al., 1999). *T. foetus*-infected cats are often misdiagnosed as having *Giardia* spp. Cats diagnosed with *Giardia* spp. on the basis of a fecal smear that fail to respond to appropriate antimicrobial therapy should be closely reevaluated for the possibility that the observed trophozoites were *T. foetus*.

DIAGNOSIS

Feline *T. foetus* infection may be diagnosed by identifying the organism in feces by direct smear examination, selective protozoal culture, and polymerase chain reaction (PCR) using species-specific primers or by observation of trichomonads in colonic mucosal biopsy specimens.

Direct Fecal Smear Examination

Fecal samples should be diarrheic and *freshly* voided or obtained directly from the rectum using a fecal loop. Areas in which feces are particularly moist or contain mucus and blood are ideal locations to sample. A scant amount of feces should be mixed in a drop of saline and examined under a coverslip using a 40× objective. Lowering the microscope condenser to increase contrast enhances visualization. Trichomonads are approximately the size of *Giardia* spp. and highly motile. The key microscopic differences between trichomonads and *Giardia* spp. are a “falling leaf” motility characteristic of *Giardia* spp. and presence of an undulating membrane on trichomonads. Multiple smears should be examined for organisms. If necessary, survival of *T. foetus* in feces can be extended from 0 to 4 days by removing adherent litter and diluting the sample with normal saline to avoid desiccation (3 ml 0.9% saline per 2 g of feces) (Foster et al., 2004). Trichomonads do not survive refrigeration and are not typically observed using fecal flotation or sedimentation techniques. Concurrent antibiotic therapy decreases the number *T. foetus* present in feces. It is often prudent to discontinue antibiotics for a few days in such cases and repeat the examination if negative results were obtained initially. The sensitivity of direct fecal smear examination for diagnosis of *T. foetus* is low (2% in cats with experimentally induced infection and 14% in cats with spontaneous disease). It can be difficult to reliably distinguish *T. foetus* from nonpathogenic trichomonads such as *P. hominis* on the basis of light microscopic appearance, making this means of diagnosis presumptive.

Protozoal Culture of Feces

If repeated direct microscopic examination results are negative for *T. foetus*, feces may be cultured in commercially available pouches marketed for diagnosis of *T. foetus* infection in cattle (In Pouch TF, Biomed Diagnostics). Pouches should be inoculated with 0.05 g (about the

size of a rice grain) of freshly voided or loop-collected feces. The pouch can be incubated either at 37° C for 48 hours or at room temperature (25° C) for up to 12 days. Bacterial overgrowth and gaseous distention of the pouch is a problem if overinoculated with feces and more common when incubated at 37° C. Pouches should be cultured upright and in the dark and examined daily (37° C) or every other day (25° C) for the presence of trichomonads. Before examination pouches should be tapped against the bench top to dislodge adherent organisms and then placed within a manufacturer-provided clamp that allows the pouch to be mounted onto the stage of a light microscope. Trichomonads are most easily found along the seams of the pouch using a 20× or 40× objective. Although feces may be shipped to some laboratories for cultivation, given the fragile nature of the organisms it is strongly recommended that this user-friendly culture technique be performed in-house for best results. Fecal culture using In Pouch TF has a detection limit of 1000 or more *T. foetus* organisms per 0.05 g of feces and is superior to direct fecal smear examination for diagnosis of *T. foetus* infection. Neither *Giardia* spp. nor *P. hominis* organisms survived in Pouch TF for longer than 24 hours in one study; thus positive cultures are strongly suggestive of *T. foetus* infection (Gookin et al., 2003). However, strictly speaking the types of trichomonads potentially hosted by cats and the specificity of In Pouch TF with regard to these other types of trichomonads are unknown. Positive In Pouch TF cultures do not preclude the possibility of coinfection with *P. hominis* or *Giardia* spp.

Polymerase Chain Reaction

A sensitive and specific single-tube nested PCR based on amplification of a conserved portion of the *T. foetus* internal transcribed spacer region (ITS1 and ITS2) and 5.8S rRNA gene from feline feces is commercially available and superior to fecal culture for diagnosis of infected cats. PCR requires approximately 180 to 220 mg of feces devoid of litter, and samples should be preserved in 3 to 5 ml of 70% isopropyl alcohol (rubbing alcohol) before shipment at room temperature. Sensitivity of the PCR is 10 trichomonads per 200-mg sample of feces (Gookin et al., 2002).

Histopathology

Colonic mucosal biopsy is often appropriate in cases of large bowel diarrhea in which less invasive diagnostics fail to identify a cause for diarrhea and appropriate empiric medical and dietary treatment trials have failed to result in a resolution of signs. Histopathology should not be relied on to make a diagnosis of *T. foetus* infection, although a diagnosis can be attained if organisms are identified. The diagnostic feature is the presence of trichomonads, which can be found in close proximity to the surface of the mucosa or in the lumen of colonic crypts. Less commonly subepithelial invasion of trichomonads may also be observed. Inflammatory infiltrates consist of plasma cells, lymphocytes, and neutrophils. Lesions can be segmental in distribution; therefore multiple sites should be biopsied. It is advisable to indicate that

T. foetus is a differential diagnosis because a minimum of six tissue sections should be examined to achieve 95% or greater confidence that trichomonads will be identified (Yaeger and Gookin, 2005).

TREATMENT

Coexisting Infectious Diseases

Any coexisting intestinal infection in a *T. foetus*-infected cat should be identified and treated if possible. Studies of experimental feline infection suggest that coexisting intestinal infection (e.g., cryptosporidiosis) worsens clinical signs of diarrhea and increases the shedding of *T. foetus* organisms. Coinfection with *Giardia* spp. is common in *T. foetus*-infected cats and, if present, should be treated (Gookin et al., 2004). If helminth parasites are not identified, empiric treatment with fenbendazole is recommended. Other infections to consider are *Cryptosporidium* spp. In most cases systemic disease or viral infections (feline leukemia virus/feline immunodeficiency virus) are not identified.

Spontaneous Resolution of Diarrhea

When left untreated, 88% of cats with *T. foetus* infection had spontaneous resolution of diarrhea within 2 years (median 9 months; range 5 months to 2 years). Time to resolution of diarrhea was significantly longer for cats from multiple-cat households and those receiving a variety of different diets and antimicrobial drugs in an attempt to treat the condition. Stressful events may be associated with a relapse in diarrhea (e.g., surgery, oral antimicrobial therapy, travel, or a change in diet). The wait-for-resolution approach to treatment of *T. foetus* infection is best suited for a stable household with a low number of cats where further spread of infection is of little concern and owners are willing to tolerate the long course of diarrhea. It is important to note that spontaneous resolution of diarrhea does not imply recovery from infection since 57% of these cats remain infected with *T. foetus* as determined by PCR when performed 2 to 5 years after diagnosis (Foster et al., 2004).

Medical Therapy

Dietary trials, homeopathic remedies, and antimicrobial drugs have not been consistently effective in ameliorating signs of diarrhea in *T. foetus*-infected cats, and studies suggest that these interventions may prolong the duration of clinical signs, perhaps by perturbing the balance of colonic microflora on which the trichomonads depend. Despite the presence of inflammatory colitis, diarrhea does not appear to be improved by treatment with corticosteroids. In vitro studies suggest that *T. foetus* is inherently resistant to many drugs or rapidly acquires resistance in vivo (Gookin et al., 2001). Trichomonads lack mitochondria and ferment pyruvate in reductive organelles called hydrogenosomes. Reduction of nitroimidazole antibiotics by hydrogenosomes results in formation of toxic anion radicals that serve as the basis for susceptibility of trichomonads to drugs such as

metronidazole. Unfortunately feline *T. foetus* infection is not responsive to metronidazole.

Ronidazole

Ronidazole (RDZ) is a 5-nitroimidazole relative of metronidazole that has been used for the treatment of *Histomonas meleagridis* (turkey blackhead), *Treponema hyodysenteriae* (swine dysentery), and *Treponema hyodysenteriae* infection (pigeon canker). RDZ has been demonstrated to be effective at killing feline isolates of *T. foetus* in vitro at concentrations greater than 0.1 mcg/ml and eradicated *T. foetus* from experimentally infected cats (on the basis of PCR) when administered at 30 mg/kg every 12 hours orally for 14 days (Gookin et al., 2006). RDZ is not registered for human or veterinary use in the United States and is currently banned from use in food-producing animals because of human hazards. Due diligence is required for protection of humans from exposure to RDZ, and veterinarians are advised to obtain informed consent before use of this drug in cats. Gloves should be worn when handling RDZ. Several pharmacies compound chemical grade RDZ for veterinary use. Because of its foul taste, compounding into gelatin capsules rather than flavored liquids is highly recommended. Storing the capsules in the freezer may improve drug stability. RDZ is popular in Europe for the treatment of *T. gallinae* in racing pigeons. Several 10% active-drug formulations for dilution in the drinking water of birds can be obtained without prescription from pigeon supply warehouses. Because of their undetermined quality, composition, and low active-drug concentration, these products are not recommended.

It is important to note that pharmacokinetic data have not been published for RDZ and that neurotoxicosis may be a common and serious side effect. Therefore treatment with RDZ should only be considered in cases of confirmed *T. foetus* infection in which informed consent has been obtained. Cats should be isolated during treatment to decrease the risk of reinfection. It is suspected that asymptomatic infections are common in multiple-cat colonies; thus isolation from cats with clinical signs alone may not be sufficient to avoid reinfection. A prolonged follow-up period is necessary to determine if infection has been eradicated. Testing by PCR at 1 to 2 weeks and 20+ weeks after completion of treatment is recommended. Negative results should be interpreted with caution since PCR cannot prove the absence of infection and prolonged asymptomatic carriage of the organism after antimicrobial therapy may be common. Until sufficient information about the pharmacokinetics and safety of RDZ is available or safer treatments are identified, isolation and treatment of individual cats rather than entire catteries is recommended if RDZ is prescribed.

CHAPTER 118

Protein-Losing Enteropathy

LISA E. MOORE, Maitland, Florida

Protein-losing enteropathy (PLE) is not a disease per se, but a term used to describe a disease that results in a nonselective loss of serum proteins into the intestinal tract. PLEs can be associated with a large number of intestinal and systemic disorders. The loss of proteins can be caused by a loss of mucosal barrier function that results in increased intestinal permeability such as inflammatory or erosive disorders or by malfunction or abnormalities of intestinal lymphatic drainage (Jeffries, 1983). PLEs are more common in the dog than in the cat. Many diseases have been reported to cause PLE in dogs, including intestinal lymphangiectasia (primary or secondary), inflammatory disorders (lymphoplasmacytic, eosinophilic, granulomatous enteritides, gluten-sensitive enteropathy), gastrointestinal ulceration, neoplasia (alimentary lymphoma, intestinal carcinoma), intestinal fungal or parasitic infections (histoplasmosis, pythiosis, trichuriasis, ancylostomiasis), foreign bodies, chronic intussusceptions, acute viral enteritis (parvovirus), acute or chronic bacterial enteritides, immune-mediated and allergic diseases (systemic lupus erythematosus), constrictive pericarditis, right-sided heart failure, and hypoadrenocorticism.

CAUSES OF PROTEIN-LOSING ENTEROPATHIES

Intestinal Lymphangiectasia

Intestinal lymphangiectasia (IL) is considered to be the most common disorder associated with PLE (Tams and Twedt, 1981; Melzer and Sellon, 2002). IL can be primary or secondary. Primary IL is a congenital disease in which insufficient or malformed lymphatic vessels result in poor intestinal lymphatic flow and drainage. Congenital IL is

considered uncommon to rare in the dog and cat. The disease can also be associated with systemic abnormalities of the lymphatic system (Fossum, 1989). Secondary IL usually results from obstruction to lymphatic flow, either in the lymphatic system (inflammatory lesions of the intestinal wall, neoplastic disorders) or subsequent to venous hypertension (congestive heart failure, portal vein thrombosis, pericardial disease). When the pressure in the lymph vessels increases, the intestinal villous lacteals dilate, become fragile, rupture easily, and leak lymph into the intestinal tract. This lymph is high in lymphocytes, chylomicrons, and proteins. The underlying disease can also limit the resorptive ability of the intestinal mucosa (Melzer, 2002). Lipogranulomas are often observed around the lymphatics in inflammatory disorders (Van Kruiningen et al., 1984).

Inflammatory Bowel Disease

Inflammatory and immune diseases of the intestines include lymphoplasmacytic, eosinophilic, and granulomatous enteritides. Lymphoplasmacytic enteritis is the most common cause of PLE in this category (Tams and Twedt, 1981; Craven et al., 2004). This disease is characterized by a diffuse infiltration of lymphocytes and plasma cells in the lamina propria of the intestinal mucosa. Inflammatory bowel disease is a chronic disorder for which no cause can be determined, but current theories are concentrating on defining immunoregulation, dietary allergens, reactions to normal enteric bacterial flora, or other chronic antigenic stimuli (Guilford, 1996; also see chapter 115). Regardless of the cause or causes, the final pathway is inflammation that results in damage to the gastrointestinal tissue, which can result in protein loss.

Breed-Related Protein-Losing Enteropathy

Breeds with a higher incidence of PLE include basenjis, soft-coated wheaten terriers, and lundehunds (Breitschwerdt, 1992; Vaden et al., 2000). These breeds appear predisposed to lymphoplasmacytic enteritis, resulting in a significant PLE. The basenji enteropathy is associated with hypoalbuminemia and hyperglobulinemia (Breitschwerdt, 1992).

Miscellaneous Disorders

As mentioned previously, various other diseases can cause gastrointestinal protein loss (Tams and Twedt, 1981; Jeffries, 1983). Conditions resulting in erosion or bleeding of the intestinal mucosa, submucosa, or muscularis can result in loss of plasma or loss of blood if the lesion is more severe. Examples would include erosion or ulceration caused by foreign objects, drugs (most commonly nonsteroidal anti-inflammatory drugs), and intussusceptions. Infiltrative disorders such as histoplasmosis and lymphoma are also reported causes of PLE. Acute and chronic infectious diseases should be included. Parvoviral enteritis can result in severe hypoproteinemia because of destruction of the villus and subsequent plasma leakage into the intestines. Various bacterial diseases, including small intestinal bacterial overgrowth, and parasitic infections can cause PLE.

CLINICAL SIGNS

Clinical signs can be variable but almost always include weight loss (loss of muscle mass and body condition). Other signs can be those associated with the gastrointestinal tract such as vomiting and diarrhea. It should be noted that not all animals with PLE have diarrhea; weight loss may be the only clinical sign. Polyphagia is seen occasionally, but many dogs and cats have variable inappetence. Other signs are related to the hypoproteinemia. Ascites, peripheral edema, and dyspnea resulting from hydrothorax all can be seen. Uncommonly some animals present with clinical signs related to thromboembolic disease such as respiratory signs caused by a pulmonary thrombus or posterior paresis caused by a distal aortic thrombus. Abdominal palpation may reveal thickened intestinal loops, lymphadenopathy, or a mass. Thoracic auscultation may reveal cardiac abnormalities.

DIAGNOSIS

The hypoproteinemia seen in animals with PLE is nonselective; therefore serum albumin and globulin levels are both decreased. Two notable exceptions include the PLE of basenji dogs (see previous discussion) and intestinal histoplasmosis. Intestinal histoplasmosis has been associated with a normal or elevated globulin fraction, presumably caused by the inflammatory response (Williams, 1996). Other abnormalities that may be noted include lymphopenia, hypocalcemia, hypomagnesemia, hypocholesterolemia, decreased antithrombin (if measured), and variably elevated liver enzymes and electrolyte abnormalities (Bush et al., 2001; Mellanby et al., 2005).

Other causes of hypoalbuminemia should be ruled out. Urinalysis and urine protein:creatinine ratio are abnormal

with renal protein loss. Decreased albumin production can be caused by severe hepatic disease, and hepatic function testing such as bilirubin and serum preprandial and postprandial bile acid analysis should be performed to eliminate this possibility. Protein loss can also occur with chronic blood loss, in which case anemia should also be present. Radiography is useful to rule out obstructive lesions (foreign objects), cardiac disease, and pulmonary metastatic or fungal lesions. Ultrasonography can be helpful to rule out mass lesions (e.g., neoplasia, pythiosis). Ultrasonographic abnormalities may be seen in animals with PLE and IL. Findings such as a corrugated small intestine and/or focal thickening of the small bowel with a loss of layering may be seen, but these changes are generally nonspecific (Moon, Biller, and Armbrust, 2003; Louvet and Denis, 2004). Hyperechoic mucosal striations seen ultrasonographically have been associated with lacteal dilation (Sutherland-Smith et al., 2007).

If all initial results are normal, the intestinal tract should be evaluated. Multiple fecal examinations (flotations and direct smears) should be performed. If all results are negative, empiric use of a broad-spectrum anthelmintic such as fenbendazole can be used before more expensive and invasive testing is carried out.

Intestinal function testing can be performed to detect malabsorption or maldigestion. Sudan staining of fecal material can be used to detect steatorrhea, which can indicate fat malabsorption. Oral D-xylose testing can indicate poor carbohydrate absorption. Cytologic examination of fecal smears or colonic scrapings may reveal fungal or protozoal organisms or leukocytes. Determination of serum folate and cobalamin levels, along with breath hydrogen and intestinal permeability testing, can further document gastrointestinal disease.

The gold standard for documenting intestinal protein loss is to quantitate radiolabeled (chromium-51) albumin in the feces after intravenous administration (Williams, 1996). For many reasons the application of this test is limited in veterinary medicine. A test that is more readily available and useful is the measurement of α -1 proteinase inhibitor (α -1-PI) in the feces (Williams, 1996). α -1-PI has a molecular weight similar to that of albumin. This protein is present in the vascular and interstitial spaces, as well as in lymph. Therefore α -1-PI can be lost into the intestinal tract in cases with PLE and is excreted in the feces intact, unlike albumin, which is broken down by bacterial degradation. Fecal α -1-PI can then be measured using an immunoassay and to provide an indirect quantitation of intestinal protein loss (Murphy et al., 2003). The assay requires collection of three separate, freshly passed fecal samples into specific preweighed tubes provided by the laboratory. This can be of value in both diagnosis and monitoring treatment (Murphy et al., 2003).

Ultimately intestinal biopsies and histopathology usually are required to define the disease process causing PLE. Endoscopic or full-thickness biopsies via exploratory laparotomy can be performed. Laparotomy provides the advantages of being able to evaluate the entire intestinal tract since some diseases may be focal and of being able to evaluate extraintestinal structures. Dilated lymphatics may be visualized as a milky weblike pattern on the serosal surface of the intestines and throughout the

mesentery. However, because animals with PLE generally are malnourished and hypoproteinemic, there is delayed wound healing that may lead to dehiscence of the intestinal anastomosis site. Accordingly, exploratory laparotomy carries a definite postoperative risk of peritonitis. In many cases endoscopic biopsies are adequate to diagnose diffuse mucosal diseases. Endoscopy allows visualization of the mucosa; dilated lacteals seen with lymphangiectasia often have the appearance of small, white pinpoint foci in the mucosa. Ileal biopsies also can be obtained endoscopically to increase the chances of finding lesions.

TREATMENT

Since hypoproteinemic animals tend to be hypovolemic because of reduced oncotic pressure, oncotic support with plasma or synthetic colloids (e.g., hetastarch, Hespan; American Critical Care) should be considered before administration of anesthesia to avoid hypotension (also see Chapter 111). Plasma also can be considered, but it is not a strong colloid unless a 20-ml/kg dose can be given, which is often not cost effective in medium- and large-breed dogs. However, plasma may be a better choice if the patient has a coagulopathy secondary to loss of antithrombin. Human albumin may also be an option if other colloids are not available, but there is a risk of allergic reaction since this is a foreign protein. The incidence of this type of reaction to human albumin in the dog is unknown.

Treatment should be aimed at any identifiable underlying disease. PLE from acute viral infections usually resolves with supportive care, and PLE caused by bacterial or parasitic infections resolves with appropriate specific therapy. Other diseases should be treated accordingly (e.g., antifungal agents for histoplasmosis, chemotherapy for lymphoma).

The mainstay of treatment for the two most common diseases causing PLE (IL and lymphoplasmacytic enteritis) is dietary control, along with antiinflammatory medication when indicated (Williams, 1996; Melzer and Sellon, 2002; also see Chapter 115). Enteral nutrition is optimal because this allows the enterocytes to repair and regenerate. Animals that cannot tolerate enteral nutrition may be fed via total parenteral nutrition or partial peripheral nutrition to stabilize them for diagnostic testing or as initial treatment for the PLE. Ultimately, though, enteral nutrition is required.

Options for enteral nutrition include elemental diets, commercially prepared foods, or home-cooked diets. Patients with severe PLE may require elemental diets initially. These diets are composed of nutrients in their elemental rather than polymeric form. They should not require significant digestion and can be easily absorbed. They usually do not contain enough protein for dogs and especially cats for long-term use, and they can be hypertonic. Several human products are available (Vivonex TEN, Sandoz Nutrition; Portagen, Mead Johnson).

Animals with less severe disease can be started on specific enteral nutrition immediately. The diet chosen should be low in triglycerides containing long-chain fatty acids, which must be transported into the circulation via the intestinal lymphatics. Short-chain triglycerides can be

absorbed directly into the portal system. The diet should also be low in lactose, easily digestible, and low in fiber. Diets high in fiber may inhibit digestion and absorption of proteins and carbohydrates. Commercially available diets can be used, or a homemade diet can be prepared (Fossum, 1989). The caloric density of the diet can be increased by adding medium-chain triglyceride (MCT) oil (Mead Johnson) or high-quality protein to the diet if needed. MCT oil is used at a dosage of 1 to 2 ml/kg/day; it may be expensive, is unpalatable to some animals, does not provide essential fatty acids, and has become controversial in recent years. It has been shown in dogs that MCTs may not be absorbed directly but may actually require normal lymphatic flow (Newton, McLoughlin, and Brichard, 2000). High-quality protein can be added in the form of cooked egg whites or low-fat cottage cheese. Alternatively one of the elemental diets can be used as a supplement (Fossum, 1989). Hydrolyzed diets may also be an alternative because they are highly digestible and low in fat and contain smaller protein particles, which are more easily absorbed.

In addition to dietary therapy, corticosteroids can prove effective in secondary IL and the inflammatory enteritides. Prednisone at a dosage of 2 mg/kg/day can be used, followed by a slow taper once a response has been seen. A maintenance dosing schedule is usually required indefinitely, preferably on an alternate-day basis. If no response is seen with corticosteroids, immunosuppressive agents such as azathioprine, cyclosporine, or methotrexate can be used (Craven et al., 2004; Allenspach et al., 2006; Yuki et al., 2006). Antibiotics may also be needed in some cases to treat intestinal bacterial overgrowth. Metronidazole and tylosin are common choices. Cobalamin may need to be supplemented parenterally (see Chapter 115 for more information about these treatments). Various electrolytes and fat-soluble vitamins may also be supplemented as needed. Prognosis can be difficult to determine because few long-term studies have been performed in dogs and cats. In general the prognosis should be guarded until a response is seen. Indefinite therapy is usually required, and relapses may occur.

CHAPTER 119

Chronic Colitis

NOLIE K. PARNELL, *West Lafayette, Indiana*

The colon plays an important role in conservation of water and electrolytes, specifically sodium and chloride, and is the major site of fecal storage until expulsion is necessary. Not as well recognized is the role of the colon in digestion and metabolism. For example, the colonic bacterial flora play an important role in the fermentation of undigested carbohydrates with the primary substrate being dietary fiber. Disruptions to the normal homeostasis of the colon leads to changes in both absorption and motility, and clinically this is often manifested as large bowel diarrhea.

Chronic colitis is a common cause of large bowel diarrhea. Chronic colitis is defined as inflammation of the colon that is present for at least 2 weeks. This chapter reviews the pathophysiology of chronic colitis, the various histologic forms of colitis, and the clinical approach I use when evaluating patients with chronic large bowel disease. A discussion of therapy is also included, and throughout the chapter, differences between the dog and cat are noted.

PATHOPHYSIOLOGY

The pathophysiology of inflammatory bowel disease is extremely complex and mostly unknown. Evidence exists that a multifactorial process occurs that involves an abnormal immune response to an antigen, whether luminal or mucosal, the commensal bacteria, and a genetic susceptibility (also see Chapter 115). The activation of CD4+ cells within the intestinal epithelium without a concomitant activation of the suppressor cells, which creates tolerance, causes inflammation (German, Hall, Day, 2003). The mucosal immune response leading to inflammation involves B and T lymphocytes, plasma cells, macrophages, cytokines, interleukins, and several inflammatory mediators (e.g., tumor necrosis factor- α , interferon- γ , nitric oxide). Although the inflammatory responses of the small and large bowel are very similar, some differences occur. For example, the immunologic response of the canine colon seems to be primarily T helper cell (Th)1 mediated, but in the canine small bowel there is a mixed response

of both Th1 and Th2. The colonic Th1 response leads to up-regulation of interferon- γ , tumor necrosis factor- α , interleukin-2, and interleukin-12. It is unknown if the feline colonic mucosal immunity acts in a similar fashion as the canine mucosal immunity.

Inflammation of the colon reduces the amount of water and electrolytes absorbed and changes colonic motility. Cytokines produced alter smooth muscle function, resulting in abnormal motor activity. Inflammation suppresses the normal colonic contractions that mix and knead, and stimulates giant migrating contractions (GMCs). GMCs are more powerful contractions that rapidly propel intestinal contents. In a normal animal these contractions only occur once to twice daily. Colonic inflammation increases the number of daily GMCs. It is believed that these GMCs are a major factor in producing the diarrhea, abdominal cramping, and increased urgency associated with colitis. Goblet cells respond to inflammation by producing increased amounts of mucus.

HISTOPATHOLOGIC TYPES OF COLITIS

Evaluation of chronic colitis histologically is difficult because of the lack of standardization and the influence of subjectivity. Colitis is usually defined histologically by the predominant inflammatory cell type present, the alterations of the normal colonic architecture (e.g., crypt collapse, goblet cell hyperplasia), and the severity of the disease process. The predominant cell types are lymphocytic-plasmacytic, eosinophilic, and granulomatous.

Lymphocytic-Plasmacytic Colitis

Lymphocytic-plasmacytic colitis is the most common form of colitis in both the dog and cat. Numerous studies have found that most dogs are middle-aged and there is no sex predilection. There may be an association between colitis in dogs and perianal fistulas, especially in the German shepherd dog. Cats with chronic colitis tend to be middle-aged, with the mean age at onset of clinical signs 5.1 years. Purebred cats were affected more often than nonpurebred cats. As with dogs, there was no sex predilection. Typically there are increased numbers of lymphocytes and plasma cells in the lamina propria, although occasionally they can be found in the submucosa and muscularis. Other inflammatory cells may also be evident histologically but not in the same numbers as lymphocytes and plasma cells. Crypt dilation, loss of surface epithelial cells, and decreased goblet cells are other histopathologic changes associated with chronic colitis.

Eosinophilic Colitis

Eosinophilic colitis is characterized by accumulations of eosinophils in the lamina propria. Diagnostics for eosinophilic colitis may reveal a peripheral eosinophilia. This finding also may be one component of feline hypereosinophilic syndrome. Compared to lymphocytic-plasmacytic colitis, eosinophilic colitis occurs uncommonly, and the animals affected tend to be younger. Endoparasites, infectious agents, and food allergy have all been incriminated in this form of colitis, but none have been proven.

Regardless, when a predominance of eosinophils is found histologically, it is prudent to investigate and eliminate these potential etiologies first since treatment of eosinophilic colitis tends to be more difficult than that of lymphocytic-plasmacytic colitis.

Granulomatous Colitis

Granulomatous colitis is characterized by the presence of macrophages and other inflammatory cells within the lamina propria. These macrophages are not periodic acid-Schiff positive, which is a discriminating feature of histiocytic ulcerative colitis (also see Chapter 120). Granulomatous colitis is rare and usually presents as a segmental, thickened, partially obstructed segment of bowel. The ileum and colon appear to be affected most commonly. Because of its histologic characteristics, it is important to eliminate inflammation secondary to fungal disease, intestinal parasites, feline infectious peritonitis, and foreign material. Treatment remains controversial, although most advocate surgical resection if possible. Medical management has variable results.

DIFFERENTIAL DIAGNOSIS

It is important to obtain a definitive diagnosis for any animal that has chronic large bowel diarrhea. Since the clinical signs of chronic colitis are similar to those of other diseases of the large bowel, it is imperative to perform diagnostics to establish a diagnosis. Although chronic colitis is a common diagnosis in a referral hospital, it is not the most common cause of large bowel diarrhea. Other more common causes of chronic large bowel diarrhea include *Trichuris vulpis* for dogs, *Clostridium perfringens*, and food hypersensitivity for both species. Other infectious agents to consider are *Histoplasma capsulatum* if geographically near the Mississippi, Ohio, or Missouri Rivers; and *Pythium insidiosum* for animals located in south and southeast. Idiopathic large bowel diarrhea is diagnosed if all test results are normal, including colonic histopathology. Neoplasia, particularly adenocarcinoma and lymphosarcoma, also causes chronic large bowel diarrhea. Both forms of neoplasia occur most commonly in older animals, although any age may be affected. Adenomatous polyps occur in dogs and are usually found on a thorough rectal examination.

Granulomatous colitis of boxer dogs, also known as histiocytic ulcerative colitis, was originally believed to be an inflammatory bowel disease of young boxer dogs (see Chapter 120). This disease differed histologically by demonstrating periodic acid Schiff–positive macrophages. Historically affected animals responded poorly to antiinflammatory and immunosuppressive therapies, and euthanasia was not uncommon. It is now believed that colonization of a selective strain of *Escherichia coli* is responsible for the inflammatory changes found on histopathology. This etiopathogenesis is further supported by the positive response these boxer dogs have to antibiotic therapy alone without the use of antiinflammatory or immunosuppressive drugs. Enrofloxacin is currently the treatment of choice for granulomatous colitis of boxer dogs.

Young cats with chronic large bowel diarrhea should be evaluated for trichomonosis (see Chapter 117). *Tritrichomonas foetus* is a flagellated protozoan parasite that causes clinical signs in a cat that is otherwise thriving. Trichomonosis is most commonly seen in purebred cats, especially Abyssinians and Bengal cats that are densely housed. *T. foetus* is frequently misdiagnosed as *Giarida* spp. Trichomonosis is histopathologically associated with mild-to-moderate lymphoplasmacytic and neutrophilic colitis. Clinical signs may resolve in some cats with no treatment, but for cases that do not, ronidazole is the current treatment of choice. Neurotoxicity has been reported in cats receiving ronidazole for the treatment of trichomonosis.

CLINICAL SIGNS AND PHYSICAL EXAMINATION

The most common clinical sign of chronic colitis is large bowel diarrhea. The characteristics of large bowel diarrhea include mucus, hematochezia (frank blood in the stool), tenesmus (straining to defecate), and occasionally pain when defecating. There is often an increased urgency and frequency of defecation, but the amount of feces per bowel movement is greatly reduced. In one study of cats with chronic colitis, hematochezia without diarrhea was the most common clinical sign. Vomiting and weight loss can occur in some cases of chronic colitis, but these tend to be the more severe cases or those that have concurrent disease that also affects the stomach or small intestine.

Historical findings may reveal a waxing or waning course of clinical signs. Initially the clinical signs may be sporadic, but progression usually occurs. The period of time during which there is large bowel diarrhea increases, and in many cases the diarrhea becomes persistent. In severe cases of chronic colitis owners may also complain that their pets are lethargic and inappetent.

The physical examination in cases of chronic colitis is usually within normal limits. In severe cases of chronic colitis or those that have concurrent disease of the small intestine, poor body conditioning suggestive of weight loss may be found. Every patient with signs of chronic colitis should have a rectal examination performed. Rectal examination may reveal an irregular or thickened mucosal surface, elicit pain, and demonstrate frank blood or mucus on the examination glove. In addition, a thorough rectal examination may discover a rectal polyp or malignant neoplasm, which can mimic the signs of chronic colitis.

DIAGNOSTIC PLAN

The diagnostic approach for chronic colitis should be systematic and thorough and include colonic biopsies. It is important to exclude all other diseases that can mimic the signs of chronic colitis. Multiple fecal examinations should always be part of the initial diagnostic plan since endoparasitism occurs more commonly than chronic colitis. Since the helminth *T. vulpis* commonly causes large bowel diarrhea in dogs, routine fecal flotations should be performed. For cats, evaluation for *T. foetus* should be performed using direct observation of trichomonads in

feces that are suspended in physiologic saline solution, by culturing feces for *T. foetus*, or using polymerase chain reaction techniques (see Chapter 117).

Rectal cytology is an invaluable diagnostic tool to eliminate other causes of large bowel diarrhea. A specimen can be collected using a gloved finger, a moistened cotton swab, or conjunctival spatula. Epithelial cells exfoliate easily; thus only minimal force is necessary when scraping the rectum and transferring the specimen to a glass slide. Normal rectal cytology should contain colonic epithelial cells, a mixed population of bacteria and yeast, and some debris. Abnormal findings include inflammatory cells, neoplastic cells, and certain infectious organisms (e.g., *H. capsulatum*). Evaluation for *C. perfringens* colitis can begin by screening fecal cytology for the presence of a large number of clostridial endospores. It has been reported that greater than five endospores per high power field may suggest the presence of *C. perfringens* enterotoxigenesis. However, there is a poor correlation between the number of endospores seen and the detection of *C. perfringens* enterotoxin (CPE) since not all endospores produce CPE. Cases of suspected clostridial colitis should be confirmed by identifying CPEs A and B in feces using a commercially available enzyme-linked immunosorbent assay after a fecal bacterial culture is performed.

I recommend a dietary trial before pursuing more advanced diagnostics such as colonoscopy. A highly digestible diet should be given exclusively for a 4- to 6-week period to determine response to the diet manipulation. Several commercially prepared prescription diets are available and include i/d (Hill's Prescription Diets), EN (Purina Veterinary Diets), Intestinal HE (Royal Canin Veterinary Diet), and Low Residue (Eukanuba Veterinary Diets). If a therapeutic diet trial does not eliminate clinical signs, supplementing the diet with soluble fiber should be attempted. It has been demonstrated that adding psyllium (Metamucil) at 1.33g/kg per day to a highly digestible diet resulted in a favorable response in greater than 85% of patients with chronic idiopathic large bowel diarrhea. Soluble fibers hold water, thereby improving the consistency of feces, stabilizing colonic motility, and altering colonic bacterial metabolism, which could manipulate the colonic flora (e.g., *C. perfringens*).

If the clinical signs persist despite these initial steps, further diagnostics are indicated. A complete blood count, biochemical profile, and urinalysis should be performed to rule out other diseases and in preparation for general anesthesia, but in the majority of cases with chronic colitis the results are normal. For cats, feline leukemia virus/feline immunodeficiency virus testing is also recommended, as well as a T_4 if it is age appropriate. Routine abdominal radiographs are also usually normal but occasionally demonstrate intraluminal narrowing, which could indicate an infiltrative disease process. In these cases the primary problem is luminal obstruction that manifests itself clinically as colitis because only a small amount of feces is able to pass through the narrowed lumen. In my practice the majority of these cases are cats with colonic lymphoma, although pathologic strictures have been seen with dogs.

Colonoscopy is indicated to visually inspect the colonic mucosal surface and obtain specimens for histopathology.

Patient preparation is essential in obtaining a reliable examination when small or subtle lesions could be missed by residual fecal material on the mucosal surface. Food should be withheld for 24 to 48 hours before the procedure. A combination of enemas and an oral colonic lavage solution, such as GoLYTELY, should adequately prepare the colon for the endoscopist. Multiple samples from the cecum, ascending, transverse, and descending colon should be obtained regardless of the gross morphologic appearance. The severity of lesions can vary at different locations, and the gross morphologic appearance of the colon does not always correlate with either the clinical signs or the histopathologic findings. A standardized system of evaluation has been proposed for both the gross morphologic findings and the histologic interpretation of colonic mucosal samples obtained endoscopically. Difficulty lies with differentiating normal colonic mucosa from mild colitis and severe lesions from lymphosarcoma.

TREATMENT

There is little evidence-based medicine in the veterinary literature regarding the management of chronic colitis. Most therapeutic protocols involve a combination of dietary and pharmacologic choices. Which diets and drugs are chosen is usually clinician dependent. Regardless of the therapy used, treatment should continue 2 to 4 weeks past resolution of clinical signs before commencing reduction of the medications given. In a study evaluating endoscopic biopsies before and after pharmacologic therapy in patients with inflammatory bowel disease of the small intestine, there were no significant changes histopathologically before or after therapy (García-Sancho et al., 2007). This study would suggest that repeating the endoscopy to obtain posttreatment biopsy samples is not necessary, although the need for posttreatment biopsy samples has not been evaluated in the colon.

Because of the intermittent shedding of ova by whipworms, therapeutic deworming should occur even if the results of the fecal examinations are negative. There are several safe and effective therapeutic options to eliminate whipworms, but my preference is fenbendazole (50mg/kg orally once daily for 3 days). If there is a positive clinical response, there is an indication to continue treatment, which includes repeating the fenbendazole treatment in 3 weeks and again in 3 months.

NUTRITIONAL MANAGEMENT

The therapeutic value of diet should not be overlooked. Loss of immunologic tolerance to either commensal luminal bacteria or food antigens potentially plays a significant role in the development of intestinal inflammation. Therefore it would be intuitive that alterations in the diet could significantly modulate inflammation. Multiple studies evaluating intestinal inflammation in both the cat and dog have shown clinical improvement with diet manipulation. Dietary therapy may also help reduce the amount of pharmacologic management used in these cases. In a study of 14 cats with colitis, six cats responded to dietary management alone, and four were treated successfully with dietary and pharmacologic management. Of the four

cats treated with a combination therapy, 60% eventually were able to be managed with diet alone. Which diet to choose is a difficult question to answer since no prospective studies comparing the different categories of diets have been performed.

Novel protein diets have been effective in controlling the clinical signs of colitis in both the dog and the cat. In a report of 13 dogs with colitis, clinical signs improved in all dogs following the introduction of a novel protein diet (Nelson, Stookey, and Kazacos, 1988). For a novel protein diet to be effective, a detailed, thorough dietary history must be obtained to determine which protein sources are indeed novel; and the chosen diet must be fed exclusively for 4 to 6 weeks without the introduction of other foods, including snacks. This may prove to be a difficult task for cats who tend to be more food selective than dogs.

Hydrolyzed diets also have been evaluated in the treatment of colitis and found to be effective. Hydrolyzed protein diets are specialized diets that disrupt the protein structure sufficiently to remove any allergens and allergenic epitopes and therefore prevent immune recognition. In one study of dogs with refractory inflammatory bowel disease, two thirds of dogs treated with a soy-based hydrolysate diet showed clinical improvement with the diet change alone. These dogs previously had failed to respond to a novel protein diet (Marks, Laflamme, and McCandish, 2002).

Other aspects of diet therapy with potential therapeutic benefit that should be considered in cases of chronic colitis include a highly digestible diet, the inclusion of ω -3 fatty acids, or soluble fiber. The benefits of soluble fiber have been discussed earlier in this chapter. ω -3 fatty acids reduce inflammation by competitively inhibiting formation of prostaglandins and leukotrienes derived from arachidonic acid.

PHARMACOLOGIC MANAGEMENT

Dietary management alone may ameliorate clinical signs in mild cases of chronic colitis, but pharmacologic therapy is usually required for the moderate-to-severe cases.

Pharmacologic management of colitis can be divided into several different categories: antiinflammatory (5-aminosalicylates), immunosuppressive (corticosteroids, cyclosporine), antimicrobial (metronidazole), and motility-modifying (loperamide). Commonly used dosages of the drugs discussed subsequently are summarized in Table 119-1.

5-Aminosalicylates

Sulfasalazine (Azulfidine; Pharmacia and Upjohn) is frequently the drug of choice for chronic colitis in dogs. Sulfasalazine is a prostaglandin synthetase inhibitor and also has antileukotriene activity. This drug consists of mesalamine linked to sulfapyridine in an azochemical bond. This linkage prevents absorption in the upper gastrointestinal tract and allows most of the drug to be transported to the large intestine. Once it has reached the large intestine, it is metabolized by cecal and colonic bacteria, releasing both components. Mesalamine acts locally on the colonic mucosa to reduce mucosal inflammation. Sulfapyridine is believed to be systemically

Table 119-1

Drugs for Treating Chronic Colitis

Drug	Dosage
Azathioprine	2 mg/kg PO q24h (C) 0.3 mg/kg PO q48h (F)
Budesonide	1 mg PO q24h (small C) 2 mg PO q24h (large C) 1 mg PO q24h (F)
Chlorambucil	2 mg/m ² PO q48h (C) 2 mg PO q48h (F)
Cyclosporine	5 mg/kg PO q24h (C)
Mesalamine	10-20 mg/kg PO TID (C)
Metronidazole	10-20 mg/kg PO BID (C, F)
Olsalazine	10-20 mg/kg PO TID (C)
Prednisone/Prednisolone	2 mg/kg PO BID (C, F) 20 mg/m ² PO BID for dogs >25 kg
Sulfasalazine	20-30 mg/kg PO TID (C) 10-20 mg/kg PO q24h (F)
Tylosin	10-40 mg/kg PO BID (C, F)

BID, Twice a day; *C*, canine; *F*, feline; *PO*, orally; *TID*, three times a day.

absorbed and therefore does not have any therapeutic effect in colitis but is blamed for the side effects of sulfasalazine. Common side effects include vomiting and keratoconjunctivitis; thus tear production should be monitored closely during treatment. Treatment should be continued for approximately 2 weeks past resolution of clinical signs. At that time a reduction of the drug can begin. I prefer a reduction schedule of 25% of the dose every 2 to 4 weeks, depending on the severity of the case.

Because of the risk of salicylate toxicity in cats, sulfasalazine is *not* used as the drug of choice in feline colitis. Salicylates are metabolized in the liver by hepatic enzymatic processes involving glucuronyl transferase. Since cats are deficient in this enzymatic pathway, salicylates have prolonged half-lives in the cat. If sulfasalazine is used in cats, it has been recommended to decrease both the frequency and the dose that is accepted in the dog.

Efforts have been made to reduce the toxicity seen with sulfasalazine. The newer 5-aminosalicylate formulations have eliminated the sulfa moiety to reduce toxicity, although keratoconjunctivitis has still been reported in the dog. Other compounds have been substituted for the sulfa moiety as the delivery vehicle to the colon. Olsalazine (Dipentum; Pharmacia) links two mesalamine molecules via an azo bond to ensure delivery to the colon. Asacol (Norwich Eaton Pharmaceuticals) and Pentasa (Marion Merrell Dow) are both mesalamine compounds. Asacol is a compound that has a pH-sensitive polymer coating that is the delivery agent. Pentasa has a timed gradual release in the distal small intestine and colon. This release in the distal small intestine is advantageous in patients that have disease in both the colon and the distal small bowel. Rowasa (Solvay Pharmaceuticals) is a 5-aminosalicylic acid containing enema, which may bring patients with severe colitis of the descending colon

immediate relief. These products have not been evaluated in the cat and therefore should be used with caution.

Glucocorticoids

Glucocorticoids in combination with dietary management and metronidazole are the treatment of choice for chronic colitis in cats. In one study of 60 cats with enterocolitis, when prednisone alone or in combination with another drug was initiated, 80% of cats had a positive response (Hart et al., 1994). Glucocorticoids may be introduced into the therapeutic plan for dogs when the previously discussed therapies are not successful in ameliorating clinical signs or if there are unwanted side effects from the 5-aminosalicylates. Combination therapy with sulfasalazine or metronidazole may reduce the dosage of glucocorticoids needed to successfully eliminate the clinical signs of chronic colitis. Prednisone or prednisolone is used most frequently because it is widely available and economical. I use an initial dosage of 2 mg/kg/day orally (or 20 mg/m² PO BID for dogs >25 kg) for 2 weeks after resolution of clinical signs before commencing a tapering schedule. Reducing the dosage of glucocorticoids by 25% every 2 to 4 weeks is usually successful in maintaining remission. If clinical signs have not resolved in 4 weeks, a change in the therapeutic plan should occur. If immediate relief of colitis is needed and the disease is located primarily in the distal colon, Cortenema (Solvay Pharmaceuticals), a hydrocortisone enema, is available.

Cats generally are tolerant of glucocorticoids and generally do not develop many side effects. However, side effects are common with dogs and include polyuria-polydipsia, polyphagia, gastrointestinal bleeding, increased susceptibility to infection, iatrogenic hyperadrenocorticism, and pituitary-adrenocortical suppression. Budesonide is a nonhalogenated glucocorticoid that has been used in the treatment of Crohn's disease in humans secondary to the concentrated local effects on the intestinal mucosa. Budesonide undergoes significant first-pass metabolism in the liver, which theoretically should reduce the side effects often seen with traditional glucocorticoids since little of the active drug is systemically available. In one study of 10 healthy dogs, the pituitary-adrenocortical axis was suppressed, but no other adverse effects were seen (Stroup et al, 2006). An enteric-coated form of budesonide is available for treatment of patients with inflammatory bowel disease.

Antimicrobials

Metronidazole is considered one of the primary pharmacologic agents in feline chronic colitis. Although categorized as an antibiotic, the therapeutic effects of metronidazole are multiple: antiprotozoal, antimicrobial, and inhibition of some aspects of cell-mediated immunity. All of these therapeutic properties are thought to be beneficial in the treatment of chronic colitis in both dogs and cats. Metronidazole is not usually used as a sole therapeutic agent but is combined either with dietary management or in combination with other pharmacologic agents. Although generally well tolerated by both species, neurologic side effects (e.g., nystagmus, ataxia, seizures) have been reported in both the cat and dog. Most neurologic

side effects are observed either with chronic therapy or at high doses. Neurotoxicosis should be reversible within 5 to 7 days after cessation of the drug.

Tylosin is a macrolide antibiotic that is used primarily in food animal production. Its spectrum of activity targets mainly facultative and obligate anaerobic gram-positive bacteria (see Chapter 116). It is also effective against some gram-negative bacteria, although *E. coli* and *Salmonella* spp. are resistant. Tylosin has been used effectively in chronic enteropathies. The reasons for its therapeutic effectiveness are most likely secondary to interference with bacterial adhesion to the mucosa and its antimicrobial and immunomodulating effects. In a study of 14 dogs with both small and large bowel clinical signs, seven of nine dogs had a rapid response to tylosin, although enteropathogenic bacteria, including *C. perfringens*, was concluded not to be the cause (Westermarck E et al, 2005). Tylosin is also well tolerated by both cats and dogs with minimal side effects. I use tylosin as a long-term alternative to metronidazole or when occasional outbreaks of diarrhea occur during treatment.

Immunosuppressive Agents

Several different immunosuppressive agents are available as adjunct therapeutics in the management of severe chronic colitis. Both azathioprine and chlorambucil are rarely used as single agents in the treatment of inflammatory bowel disease and are used mostly in combination with glucocorticoids. The serious side effects of azathioprine in cats (myelosuppression and hepatotoxicity) severely limit its use in feline colitis, but chlorambucil has been shown to be efficacious in refractory cases of feline inflammatory bowel disease. Cyclosporine has been shown to be an effective alternative drug in dogs with steroid-refractory inflammatory bowel disease. It has not been evaluated in the cat. Cyclosporine suppresses activated T cells in the intestinal mucosa by inhibition of interleukin-2, which ultimately reduces the amount of proinflammatory cytokines. In a study of 14 dogs with severe inflammatory bowel disease, 78% (11 out of 14) of the dogs positively responded to the drug, with 9 of the 11 dogs considered to be in complete remission of clinical signs (Allenspach et al., 2006). Side effects of cyclosporine include gastrointestinal disturbances, gingival disease, and alopecia.

PROGNOSIS

The short-term prognosis for chronic colitis is good for both the dog and the cat, although most reports indicate that cats have a slightly better overall response rate. Long-term prognosis for complete resolution, no relapses,

and no chronic treatment seems to be poor. Most cases of inflammatory bowel disease are not curable, and the owner should be educated that most likely some form of treatment will be necessary long term. Fortunately for some animals, especially feline patients, dietary management alone may be a possibility for long-term management of chronic colitis.

Canine Ulcerative Colitis

KENNETH W. SIMPSON, *Ithaca, New York*

Histiocytic ulcerative colitis (HUC) (also known as granulomatous colitis) is a severe inflammatory disease of unknown etiology that typically affects boxer dogs under 4 years of age. Others breeds such as mastiff, Alaskan malamute, Doberman pinscher, and French bulldogs are affected sporadically.

PATHOPHYSIOLOGY

From a comparative perspective it is clear that HUC in dogs has features in common with spontaneous idiopathic inflammatory bowel diseases in humans, such as ulcerative colitis (macroscopic appearance, regional distribution, immunopathology), Crohn's disease (granulomatous inflammation, bacteria within macrophages, response to fluoroquinolones) and Whipple's disease (PAS-positive macrophages, bacteria within macrophages); but it is not identical to any one of these diseases.

Evidence is mounting that inflammatory bowel disease in humans is a consequence of an abnormal host response to the enteric bacteria that can be viewed as normal flora or opportunistic pathogens (Hanauer, 2006). With this thought in mind two studies have recently explored the possibility that an uncharacterized infectious agent such as *Tropheryma whippelii* (the causative agent of Whipple's disease) or an abnormal mucosa-associated flora is involved in the etiopathogenesis of HUC in boxer dogs. One of these studies used a combination of culture-independent molecular techniques (16srDNA sequencing and fluorescence in situ hybridization) to examine the mucosa-associated bacterial flora of colonic biopsies from healthy dogs, dogs with lymphoplasmacytic colitis, and boxer dogs with HUC. Those investigators demonstrated selective intramucosal colonization of HUC biopsies by *Escherichia coli* (Simpson et al., 2006). Another study described the immunolocalization of *E. coli*, *Lawsonia intracellularis*, *Campylobacter*, and *Salmonella* to macrophages in the colon of 10 of 10, 3 of 10, 2 of 10, and 1 of 10 boxer dogs with granulomatous colitis, respectively (dogs without colitis or other forms of colitis were not examined) (Van Kruiningen et al., 2005). These findings strongly suggest that HUC is a consequence of mucosal colonization by luminal *E. coli* in a susceptible individual (i.e., an undefined breed-specific abnormality in boxer dogs).

Interestingly, the *E. coli* strains isolated from the colonic mucosa of dogs with HUC adhered to, invaded, and persisted in cultured epithelial cells to the same degree as *E. coli* strains associated with Crohn's disease. Initial investigations of HUC and Crohn's-associated *E. coli* indicate that they are more similar in phylogeny and virulence gene profiles to extraintestinal pathogenic *E. coli*

(e.g., uropathogenic *E. coli*) than diarrheagenic *E. coli* and point to the association of *E. coli* that resembles extraintestinal pathogenic strains in genotype with chronic intestinal inflammation (Simpson et al., 2006).

CLINICAL AND PATHOLOGIC FEATURES

Dogs are usually presented for the investigation of frequent bloody mucoid stools and weight loss. Clinicopathologic abnormalities generally are limited to anemia and hypoalbuminemia. Abdominal ultrasonography may show thickening of the colon and regional lymphadenopathy. Lymph node aspirates may contain histiocytes. Colonoscopy is frequently characterized by thickening and ulceration of the colon (Fig. 120-1, A).

The dominant histologic features of colonic biopsies are loss of colonic epithelium and goblet cells and the accumulation of large numbers of periodic acid-Schiff (PAS)-positive macrophages (Fig. 120-1, B and C). The PAS-positive material is thought to be derived from remnants of bacterial cell wall glycoprotein, and the accumulation of PAS-positive material in macrophages may be caused by defective phagocytosis. Immunopathologic studies describe an increase in immunoglobulin (Ig)G₃ and IgG₄ plasma cells, CD3 T cells, L1 and major histocompatibility complex (MHC)II-positive cells (German et al., 2000).

Several studies have described bacteria within the mucosa of affected dogs; but known enteropathogens such as *Salmonella*, *Campylobacter Yersinia*, and *Shigella* have not been isolated (Van Kruiningen et al., 1965). Ultrastructural studies suggest active phagocytosis of bacteria that in some instances resemble *Chlamydia*. An attempt to reproduce colitis in boxer dogs with *Mycoplasma* isolated from the colon and regional lymph nodes of four affected dogs was unsuccessful. The predilection for boxer dogs, with only sporadic cases of this type of colitis reported in non-boxer dogs, and absence of a causal infectious agent have led to HUC being considered a breed-specific, immune-mediated disease of unknown etiology.

TREATMENT

In contrast to the widely accepted view that HUC is an incurable immune-mediated disease, the original description by Van Kruiningen (1965) describes a favorable outcome in six of nine dogs treated with chloramphenicol. The results of three recent studies provide clear evidence of clinical and histologic remission in 12 boxer dogs and 1 English bulldog treated with antibiotic regimens containing fluoroquinolones (Davies et al., 2004; Hostutler et al., 2004). Treatment with enrofloxacin

Fig. 120-1 Clinical and pathologic features of granulomatous colitis of boxer dogs. **A**, Colonoscopy shows a diffusely thickened and ulcerated mucosa (arrow). **B**, Histologically there is severe loss of glandular structure and cellular infiltration (H&E). **C**, Mucosal infiltration with PAS staining foamy macrophages (inset) is a dominant feature. (Reproduced from Simpson KW et al: Adherent and invasive *Escherichia coli* is associated with granulomatous colitis in boxer dogs, *Infect Immun* 74:4778, 2006.)

alone or in combination with metronidazole and/or amoxicillin was generally reported to induce resolution of clinical signs within 2 weeks. Approximately one third of dogs remained free of clinical signs during a 5- to 14-month follow-up after discontinuation of treatment. In the remaining dogs clinical remission was maintained by continuing enrofloxacin at dosages ranging from 68 mg

Fig. 120-2 Colonic biopsies of a boxer dog with granulomatous colitis before (**A**) and after (**B**) clinical remission induced by enrofloxacin.

orally every 24 hours to 68 mg orally every 72 hours for between 2 to 21 months. A few dogs relapsed, and remission was achieved by retreatment with enrofloxacin. Repeated biopsy specimens were obtained from eight dogs after treatment, and all showed marked histologic improvement (Fig. 120-2). Resolution of clinical signs and colitis was associated with eradication of intramucosal *E. coli* (Simpson et al., 2006).

It is noteworthy that one dog started on enrofloxacin at 6 months of age developed carpal lameness after approximately 1 year of therapy. Cartilage abnormalities have been described in young dogs receiving enrofloxacin, and this is clearly of concern. This dog continued to receive enrofloxacin 68 mg orally every 72 hours for 6 months after the diagnosis of lameness, and no other complications secondary to long-term therapy were noted. Alternative antibiotics have not been evaluated, but azithromycin and chloramphenicol are possible considerations.

CHAPTER 121

Flatulence

PHILIP ROUDEBUSH, Topeka, Kansas

Flatulence is defined as excessive formation of gases in the stomach or intestine and is usually associated with noticeable flatus, belching, borborygmus, abdominal distention, or a combination of these clinical signs. *Flatus*, rather than flatulence, is the term that should be used for gas expelled through the anus. *Belching* is the noisy voiding of gas from the stomach through the mouth, whereas *borborygmus* is a rumbling or gurgling noise caused by the propulsion of gas through the intestines.

Excessive flatus is a chronic objectionable problem that occurs often in dogs and less often in cats. Although belching, borborygmus, and abdominal distention are less common complaints of pet owners, routine questioning may elicit their presence. Flatus, belching, and borborygmus occur in normal pets but may also develop as a consequence of gastric, small intestinal, or colonic disorders. At times excessive flatus is the primary reason pet owners seek veterinary advice.

PRODUCTION OF INTESTINAL GAS

The tendency to treat flatus as a humorous topic has obscured appreciation of the complex physiology that underlies the formation of intestinal gas. The quantitatively important gases in the intestinal tract are nitrogen (N_2), oxygen (O_2), hydrogen (H_2), carbon dioxide (CO_2), and methane (CH_4). These odorless gases comprise more than 99% of the intestinal gas volume in people and pet animals (Table 121-1). The characteristic unpleasant odor of intestinal gas comes primarily from the presence of trace gases that contain volatile sulfur compounds such as hydrogen sulfide (H_2S), methanethiol (CH_3SH), and dimethylsulfide (CH_3SCH_3). The noxious odor of flatus in

both humans and dogs correlates most strongly with the concentration of hydrogen sulfide.

Gas in the gastrointestinal (GI) tract is normal and is derived from four primary sources (see Table 121-1): aerophagia (O_2 and N_2); interaction of gastric acid and alkaline food, saliva, or pancreatic bicarbonate (CO_2); diffusion from the blood (CO_2 , N_2 and O_2); and bacterial metabolism/fermentation (CO_2 , H_2 , CH_4 and a variety of trace gases, including volatile sulfur compounds). Gases can be removed from the gut via passage out the esophagus or anus, diffusion into the blood, and consumption by bacteria. The net of these processes proximal to a given site in the GI tract determines the volume and composition of gas passing that site.

Swallowed air is thought to contribute the most to gas in the digestive tract. Air can enter the stomach in association with the swallowing of liquids or solids. Studies using ultrafast computed tomography in humans show that a mean of 17 ml of air accompanies the swallowing of 10 ml of water. Given the quantity of food and fluid ingested each day, large amounts of air may normally enter the stomach. If not belched, swallowed air passes through the GI tract with minimal absorption and is often passed per rectum. Air can also be swallowed in the absence of food or water ingestion via the propulsion of a bolus of air into the pharynx. This may be the cause of excessive flatus commonly seen in many brachycephalic breeds. Vigorous exercise and rapid and competitive eating situations may exacerbate aerophagia. Intestinal transit time is considerably shorter for gases than for liquids or solids. Air introduced into the stomach can result in flatus within 15 to 35 minutes. It has been estimated that gases can move 10 cm per second through the GI tract. The interaction between hydrochloric acid and alkaline food, saliva, or bicarbonate

Table 121-1

Types and Sources of Intestinal Gas

Gases	Source
Quantitatively Important Intestinal Gases	
Nitrogen (N ₂)	Swallowed air Diffusion from blood
Oxygen (O ₂)	Swallowed air Diffusion from blood
Hydrogen (H ₂)	Bacterial fermentation (large intestine)
Carbon dioxide (CO ₂)	Diffusion from blood Bacterial fermentation (large intestine) Gastric acid + food, saliva or bicarbonate
Methane (CH ₄)	Bacterial fermentation (large intestine)
Odoriferous Gases	
Volatile sulfur compounds (hydrogen sulfide, methane-thiol, dimethylsulfide)	Bacterial fermentation (large intestine)

secreted by the pancreas produces carbon dioxide in the stomach and intestines. Belched gas is largely swallowed air plus variable quantities of carbon dioxide.

A large amount of gas is formed from bacterial fermentation in the colon. Substrates for bacterial gas production include dietary substances (fiber, poorly digestible protein, and carbohydrate), and endogenous sources (mucin, bile acids). Foods that contain large amounts of nonabsorbable oligosaccharides (e.g., raffinose, stachyose, verbacose) are likely to produce large amounts of intestinal gas. Dogs and cats lack the digestive enzymes needed to split oligosaccharides into absorbable monosaccharides. Therefore bacteria in the colon rapidly ferment these sugars, producing hydrogen and carbon dioxide. Soybeans, beans, peas, and other legumes contain large quantities of nonabsorbable oligosaccharides and are often associated with excessive flatus. Many fibers used in pet foods are fermented by colonic microflora and may contribute directly to flatus. Rapidly fermentable fibers in pet foods include pectins and most gums. Fiber-containing foods may contribute to flatus indirectly through reduced dry matter digestibility. Intestinal gas production is also increased by fresh or dried foods containing fructose, resistant starches, and fermentable fiber (e.g., apples, grapes, prunes, raisins, bananas).

Diseases that cause maldigestion or malabsorption are often associated with borborygmus, abdominal distention, and excessive flatus because large amounts of malassimilated substrates are available for bacterial fermentation. Flatus is also frequent in adult dogs and cats fed excessive amounts of lactose-containing foods.

Sulfur-containing gases are the major malodorous components of human and canine flatus. Dietary sources of sulfur (sulfates and sulfur-containing amino acids), and endogenous sulfur-containing compounds (e.g., mucin, taurocholate) are converted by sulfate-reducing bacteria to the odoriferous compounds hydrogen sulfide, methanethiol, and dimethylsulfide. Onions, nuts, spices,

cruciferous vegetables (e.g., broccoli, cabbage, cauliflower, Brussels sprouts), and carrageenan contain high levels of sulfate and often increase production of malodorous gases. High-protein ingredients may also increase malodorous gas production.

ASSESSMENT OF PATIENTS WITH FLATULENCE

Pet owners often express concerns with clinical manifestations of flatulence and may describe an increase in frequency of belching, flatus, or borborygmus, objectionable odor of flatus, or abdominal distention. In one study 43% of dog owners reported flatus in their otherwise healthy pet dogs, and 13% of owners reported objectionable odor associated with the flatus episodes (Jones et al., 1998). Dogs housed indoors and less active dogs were more likely to have evidence of flatus. Temperament, frequency of feeding, specific diet, eating habits, age, gender, and history of previous GI disease were not found to be risk factors for flatulence in this particular study.

At times it may be possible to elicit a history of dietary change or dietary indiscretion in association with flatulence. Specific foods, major food ingredients, treats, supplements, and opportunities for dietary indiscretion should be evaluated. A thorough assessment should also include verification of the feeding method currently used. Items to consider include feeding frequency, amount fed, how the food is offered, access to other food (e.g., a dog eating food for cats in the same household), relationship of feeding to exercise, and who feeds the animal.

There is widespread belief that some individuals are consistently more flatulent than others. This is probably true since studies in humans have shown great variability in the frequency of flatus and such variation probably occurs in pet animals as well. Rectal gas excretion rates in humans range from 400 to 1500 ml/day (mean 705 ml/day). Humans eating their usual diet passed gas per rectum an average of eight to 10 times per day with an upper normal limit of 20 times per day. In general, frequency of flatus correlates with volume of intestinal gas; thus increases and decreases in episodes of flatus can be used to obtain a relative idea of changes in intestinal gas volume. Frequency of gas passed per rectum has not been evaluated in pets whose owners have complained of problems with flatus.

Belching, abdominal distention, and flatus may develop in conjunction with other GI signs, including weight loss, diarrhea, and steatorrhea. This type of history is very suggestive of an underlying small intestinal disorder. Examples of chronic intestinal disorders often associated with flatulence include exocrine pancreatic insufficiency, inflammatory bowel disease, small intestinal bacterial overgrowth, wheat-sensitive enteropathy, food sensitivity, and lymphangiectasia. In one study 26% of cats with chronic diarrhea and/or vomiting had flatus, and 11% of these cats had abdominal distention (Guildford, 2001). Cats with clinical evidence of flatulence should always be evaluated closely for underlying chronic GI problems such as inflammatory bowel disease or food sensitivity.

Excessive aerophagia is a risk factor for flatulence and is seen with brachycephalic working and sporting canine breeds and dogs with aggressive and competitive eating

behaviors. Dietary indiscretion and ingestion of certain pet food ingredients may be risk factors for certain individuals. Excessive belching, rapid eating, and aerophagia have also been identified as risk factors for gastric dilation-volvulus (GDV) syndrome and should be considered important clinical findings in dogs at risk for GDV syndrome.

In many cases physical examination findings are unremarkable in dogs and cats with flatulence. Intestinal gas often can be detected during abdominal palpation, but it is difficult to assess the quantity of gas from palpation alone. Laboratory testing is usually not indicated. Animals may be in poor body condition if objectionable flatus occurs secondary to an underlying GI condition. Further evaluation is in order if concomitant vomiting, diarrhea, or weight loss is present.

FEEDING PLANS FOR PATIENTS WITH FLATULENCE

Dietary management of flatulence is primarily concerned with decreasing intestinal gas production by bacterial fermentation of undigested food (Box 121-1). In general, animals with excessive or objectionable flatus benefit from highly digestible foods (dry matter digestibility >90%) offered in small frequent meals. This protocol reduces food residues available for bacterial fermentation in the large intestine and should reduce gas production.

Box 121-1

Summary of Feeding Plans for Patients With Flatulence

1. Control aerophagia.
 - Feed several small meals daily.
 - Discourage rapid or competitive eating.
 - Feed a mixture of moist and dry foods.
 - Surgically correct stenotic nares and elongated soft palate in brachycephalic dogs.
2. Decrease intestinal gas production.
 - Feed a highly digestible food (dry matter digestibility >90%).
 - Change to food(s) with rice as the sole or predominant carbohydrate source.
 - Avoid food(s) containing ingredients from legumes, such as soybean meal, soybean mill run, peas, pea fiber.
 - Eliminate vitamin, mineral, or fat supplements.
 - Avoid foods or treats containing lactose (e.g., cheese, milk, ice cream).
 - Avoid fresh or dried fruit.
3. Decrease substrates for noxious gas production.
 - Change the dietary protein source(s).
 - Decrease dietary protein levels.
 - Eliminate vitamin, mineral, or fat supplements.
 - Avoid onions, nuts, spices, or cruciferous vegetables (broccoli, cabbage, cauliflower, Brussels sprouts).
 - Avoid canned pet foods that contain carrageenan.
4. Walk dog outdoors within 30 minutes of meals to encourage defecation and elimination of intestinal gas. In general, more activity and exercise results in fewer problems with flatus.
5. If changes in the feeding plan do not result in significant improvement, consider use of carminitives.

Certain protein, carbohydrate, and fiber ingredients or levels may affect flatus production in individual animals. Of the numerous foods alleged to enhance flatus in people, baked beans are the only natural food that have been carefully studied. Flatulent animals may benefit from eating foods that do not contain a source of legumes such as soybean meal, soybean mill run, soy hulls, peas, pea fiber, or pinto beans.

Changing the sources of dietary protein or carbohydrate may benefit some flatulent individuals. In general, aerophagia and dietary carbohydrate contribute most to the volume of intestinal gas, whereas dietary protein sources contribute to odoriferous gases. Reports in humans confirm that a diet in which all carbohydrate is supplied by white rice reduces intestinal gas formation. Studies in dogs also suggest that intestinal gas production is lowest for foods containing rice as the carbohydrate source when compared to other carbohydrate sources such as wheat or corn. Therefore use of commercial or homemade foods containing rice as the major or sole carbohydrate source is a prudent recommendation for flatulent dogs and cats. For example, changing from a commercial dry food that contains corn, chicken meal, and soybean meal to a dry food that contains lamb meal and rice may be helpful.

In addition, vegetarian-based foods containing strongly flavored, sulfur-containing vegetables or legumes should be avoided in patients with flatulence. In some cases reducing dietary protein content alleviates odoriferous flatus. In most cases vitamin-mineral supplements should be avoided because these products may alter intestinal microbial activity. The lactose content of food and treats (e.g., cheese, ice cream, milk) may be a factor in adult animals, and lactose-containing foods should also be eliminated from the diet. Foods that are high in fructose, resistant starch, and/or fermentable fiber should be avoided. A series of dietary trials is often successful in finding a food that lessens excessive flatulence or objectionable flatus in individual pets.

Reducing aerophagia is important in the control of flatulence in dogs, especially in brachycephalic breeds. Several small meals should be fed daily in an effort to discourage rapid eating and gulping of air. Feeding in a quiet, isolated location eliminates competitive eating and reduces aerophagia. These same feeding methods plus feeding a mixture of moist and dry foods may be helpful in reducing the risk of GDV in dogs. Surgical correction of stenotic nares and overlong soft palates may help reduce aerophagia in some brachycephalic dogs.

Simple changes to feeding routines may also improve objectionable flatus. If possible, dogs should be walked outdoors within 30 minutes of meals. This will encourage defecation and elimination of intestinal gas and lessen indoor effects of unwanted flatus. As mentioned previously, less active dogs are at higher risk of having objectionable flatus.

CARMINITIVES

Carminitives are medicines or preparations that relieve flatulence. Various herbal and botanical preparations have been used for thousands of years as carminitives. More recently commercial products have been introduced that claim to

reduce or control flatulence. These products can be used in conjunction with changes in the feeding plan and usually contain activated charcoal, bismuth subsalicylate (BSS), zinc acetate, simethicone, *Yucca schidigera* preparations, α -galactosidase, pancreatic enzyme supplements, probiotics, or various herbal/botanical preparations. Nonabsorbable antibiotics such as neomycin and rifaximin also have been shown to reduce flatulence and the number of flatus episodes in healthy people and dogs. However, routine use of nonabsorbable antibiotics in otherwise healthy pet animals with flatulence is not indicated.

Dry activated charcoal adsorbs virtually all odoriferous gases when mixed directly with feces and flatus gas. However, ingestion of activated charcoal by humans has not been effective in reducing the number of flatus events, volume of intestinal gas released, odor of feces, or breath hydrogen excretion after bean ingestion. In vitro studies suggest that the failure of ingested charcoal to reduce liberation of volatile sulfur compounds is because of the saturation of charcoal binding sites during passage through the gut. Uptake of sulfur-containing gases is slowed considerably by wetting of activated charcoal. Activated charcoal is found in a number of commercial canine treats purported to control flatulence.

BSS reduces fecal and flatus odor in humans when given frequently (four times daily). Bismuth is the active ingredient and avidly adsorbs hydrogen sulfide, forming insoluble bismuth sulfide. Bismuth sulfide imparts a characteristic black color to feces. Bismuth also has antibacterial activity, which may account for some of its effects. BSS is found in various commercial veterinary antidiarrheal-adsorbent products, as well as in over-the-counter antidiarrheal products for human use (e.g., Pepto-Bismol). BSS may be effective in controlling objectionable flatus in pet animals but probably needs to be given multiple times per day, which precludes its practical long-term use. BSS should be used with caution in cats because of concerns with salicylate toxicosis.

Similar to bismuth, zinc acetate binds sulphydral compounds and has also been shown to reduce volatile sulfur compounds when exposed directly to flatus gas. Addition of zinc acetate to food (1% total diet) decreased fecal hydrogen sulfide concentrations and improved flatus odor in rats. One report showed that an oral treat containing zinc acetate, activated charcoal, and *Yucca schidigera* extract reduced highly odoriferous episodes of flatus in dogs (Gifford et al., 2001).

Simethicone (dimethylpolysiloxane) is an antifoaming agent that reduces surface tension of gas bubbles and is found in commercial veterinary products and over-the-counter products for human use. Why simethicone would be beneficial in patients with flatulence is not obvious; however, one could speculate that altered gas bubbles might be more effectively eliminated. In general, simethicone has no effect on total daily flatus volume, number of flatus episodes, or average volume per flatus event in people. Simethicone may help reduce gastric accumulation of gas and alleviate upper GI symptoms. The effectiveness of simethicone in controlling flatulence in pet animals is unknown. It would not be expected to control objectionable flatus odors.

Extracts of the *Yucca schidigera* plant have been used to control fecal malodor in animal waste lagoon systems

and may help decrease fecal aroma. The mechanisms of action are poorly understood and may include "binding" of ammonia or alterations in microbial activity. In the United States *Yucca* preparations are only approved as flavoring agents in pet foods, and it is unknown whether they effectively control flatulence or objectionable flatus odors when ingested by pet animals.

Products containing α -galactosidase are available as human (Beano) and veterinary (CurTail) products. They reduce flatus volume by improving digestion of nonabsorbable oligosaccharides found in soybeans, beans, pea, and other legumes. These products would not be expected to improve excessive flatus from other causes (e.g., aerophagia) or the odor of flatus. Anecdotal reports suggest that these products may be beneficial in some animals.

Pancreatic enzyme supplementation has been shown to decrease abnormal intestinal gas production in dogs with exocrine pancreatic insufficiency. Pancreatic enzyme preparations have also been widely used for bloating and abdominal distention in people. Because ingestion of these preparations should add little to the enzyme output of the pancreas in otherwise normal individuals, there is no solid rationale for their use in flatulent patients without pancreatic disease. Nevertheless, one study in humans showed that a microencapsulated pancreatic enzyme preparation significantly reduced postprandial symptoms of bloating and abdominal distention experienced by healthy humans ingesting a high-calorie, high-fat meal. This finding suggests that pancreatic enzyme supplements might benefit some patients with flatulence.

Use of probiotic supplements containing various live bacterial cultures has been shown to improve flatulence in some humans with irritable bowel syndrome or functional abdominal bloating (feeling of fullness or bloating without another functional GI disorder). No studies have evaluated use of probiotic preparations in animals with flatulence. More than 30 herbal and botanical preparations have also been listed as carminitives. The dosage, safety, and efficacy of herbal/botanical preparations in pets with flatulence have not been established.

To date the best evidence is available for short-term use of BSS, zinc acetate, and nonabsorbable antibiotics as carminitives. Less evidence can be found for use of activated charcoal, simethicone, digestive enzyme preparations, *Yucca* extract, probiotics, and herbal preparations. Changing the feeding plan (food and feeding method) rather than using carminitives offers the best opportunity for successful long-term management of flatulence in pet animals.

MONITORING PATIENTS WITH FLATULENCE

Patients should be evaluated for evidence of maldigestion or malabsorption if feeding methods and ancillary therapy outlined in this chapter are not successful in reducing or controlling flatulence. Relapses in animals that have been previously asymptomatic often indicate dietary indiscretion. The prognosis for control of flatulence is good in most cases. However, pet owners should be educated about normal intestinal gas production and not expect complete cessation of flatulence, especially in

pets with excessive aerophagia. In some cases the following advice may still be necessary: "After trying empirical therapy for pets with chronic flatulence, sound advice for the client is to always stand upwind from the patient" (Lorenz, 1974).

CHAPTER 122

Anal-Rectal Disease

CRAIG B. WEBB, Fort Collins, Colorado

Anal-rectal disorders of the dog and cat are rarely life threatening unless caused by malignancy. Diseases found in this area are often painful for the patient and difficult for the owner to manage; and they frequently result in secondary complications such as constipation, diarrhea, or fecal incontinence. The patient's quality of life can be severely affected and, because many of these conditions fail to respond adequately to attempts at intervention, could result in a decision to euthanize the pet.

ANATOMY

The rectum is a continuation of the colon that begins at the pelvic inlet and ends at the anal canal. Inflammation of the rectal mucosa results in an increase in goblet cell mucus secretion, tenesmus, and dyschezia. The anal canal extends from the rectum to the exterior anal opening. Surrounding the anal canal, the internal anal sphincter is composed of involuntary smooth muscle, and the external anal sphincter is composed of skeletal muscle. Innervation of this area is provided by both divisions of the autonomic nervous system: parasympathetic nerve fibers control defecation (contraction of the rectum, relaxation of the internal anal sphincter muscle), whereas sympathetic nerve fibers control storage of feces (relaxation of the rectum, contraction of the internal anal sphincter). Striated muscles of the external anal sphincter

are innervated by a branch of the pudendal nerve. Damage to this nerve and loss of external anal sphincter function result in fecal incontinence. Muscles of the pelvic diaphragm (sacroccygeal and levator ani) are also important in maintaining normal anal-rectal anatomy and function.

ANAL DISEASE

Atresia Ani

Atresia ani (anal agenesis) is a congenital condition that carries with it a grave prognosis. The absence of a normal anal opening may become apparent even before weaning; signs are associated with tenesmus, a bulging perineum, abdominal distention, and discomfort. The presence of an alternate route of evacuation from a rectovaginal, rectovestibular, or rectourethral fistula may lessen the clinical signs and delay the diagnosis. Surgical correction is the only therapeutic option and is often accompanied by complications such as dehiscence, fecal incontinence, or anal-rectal stricture formation. A surgical technique designed to preserve an existing fistula along with the sphincter musculature has shown promising long-term results in several dogs, but concurrent megacolon may become a limiting factor, even in patients that undergo successful surgical correction of the anal opening.

Although this condition is most often diagnosed in dogs, there is a report of atresia ani with concurrent rectovaginal fistula in three kittens, two of which were Manx littermates.

Anal Sacculitis

Anal sac disease is rare in cats but common in dogs and is usually diagnosed based on historical findings and a thorough physical examination of the area (see also Chapter 107). Affected dogs exhibit any number of behaviors that suggest that the anal area is painful such as scooting, licking, or painful defecation. Examination of the region may reveal anal sac contents that are resistant to manual expression; a palpable mass; obvious inflammation; or even abscessation, rupture, or draining fistulas. The chronicity of disease and presence of impaction or secondary infection may determine the degree of inflammation and dictate the treatment requirements. Manual extrusion of the anal sac contents, flushing with saline, and infusion with antibiotics and steroid ointments may suffice in simple cases, but systemic antibiotics are required for more involved or chronic cases. All patients benefit from proper nursing care, including frequent gentle expression of the anal sac contents, warm compresses, and attention to hygiene. Abscessed anal sacs should be addressed surgically, providing adequate drainage and abscess management. Recurrence of significant anal sacculitis may warrant complete surgical removal of the anal sacs.

Anal Sac and Perianal Neoplasia

Adenocarcinoma of the Apocrine Gland of the Anal Sac

Adenocarcinoma of the apocrine gland of the anal sac is a malignant, locally aggressive neoplasm that has metastasized frequently by the time of diagnosis (see also Chapter 83). It was previously thought that anal sac adenocarcinomas were most common in older spayed female dogs, although recent surveys suggest that neither gender nor reproductive status is a predisposing factor. These tumors have metastasized in over half of the cases at the time of diagnosis, most often to sublumbar lymph nodes. Common clinical signs include tenesmus, constipation, anorexia, and weight loss. Some patients exhibit polyuria/polydipsia secondary to tumor-induced hypercalcemia from the production of a parathormone-related protein (PTHrp). Because of this relationship, unexplained hypercalcemia in a case should initiate a rectal examination for the possibility of this tumor. A wide variety of treatment options have been investigated, including surgery, chemotherapy, radiation, and various combinations thereof. With surgery alone survival time appears to be between 10 and 20 months. The prognosis may be decreased if hypercalcemia or metastatic disease is present or if the tumor is greater than 10 cm² in size. Survival time is also shorter in dogs treated with only chemotherapy. One report suggests that combining tumor resection with iliac lymph node removal prolongs survival if the tumor is not locally invasive, whereas another survey concluded that there was no difference in median survival of dogs with sublumbar metastases compared to those without. Multiple sequential surgeries have also been used to prolong survival time. Combining surgical

excision of the anal sac with sublumbar lymph node removal and melphalan chemotherapy resulted in a modest increase in survival times; and the combination of surgery, radiation, and mitoxantrone appeared to increase survival time in a number of dogs.

There is one report of an anal sac adenocarcinoma in a 12-year-old male neutered Siamese cat (Mellanby et al., 2002). The cat presented with a history of inappetence, lethargy, and an enlarged left anal sac, which was surgically excised. The neoplasia returned 4 months later, and the cat was euthanized.

Perianal Adenomas

Perianal adenomas are the most common perianal tumor, appearing most often in intact male dogs, suggesting hormonally mediated growth. These tumors are not associated with paraneoplastic syndromes (i.e., the hypercalcemia seen with anal sac adenocarcinomas) or metastatic disease, nor are they considered a premalignant condition. Treatment includes castration and surgical removal and carries with it an excellent prognosis.

Other Tumors

Other tumor types reported in the anal and perianal region of dogs are rare and include benign cystadenoma, malignant melanoma, squamous cell carcinoma, and malignant perianal sebaceous gland adenocarcinoma in addition to soft-tissue sarcoma, leiomyoma, lymphoma, and mast cell tumor. Perianal tumors are rarely found in the cat.

Anal Furunculosis

Anal furunculosis, more commonly referred to as perianal fistula disease, is a progressive inflammatory condition characterized by perianal ulceration and sinus tract formation. As with most anal diseases, clinical signs include tenesmus; excessive licking of the area; tail chasing; or abnormal tail carriage, hematochezia, and dyschezia. The clinical condition may progress to include weight loss, lethargy, constipation, fecal incontinence, diarrhea, and purulent discharge and is usually associated with significant discomfort. German shepherds are predisposed; however, the condition has been described in other breeds, including Labrador retrievers, Irish setters, Old English sheepdogs, and collies. The etiology underlying perianal fistula disease is unknown; possible contributing factors include the anatomy of the area in certain breeds, infectious agents, and endocrine or hormonal influences. The disease is also likely to be a clinical manifestation of an underlying immune system dysfunction; whether that is an immunoglobulin A deficiency, abnormal antigen-presentation, or a specific T cell dysfunction remains to be determined. Historically perianal fistula disease has been considered very refractory to medical management, but recent therapeutic protocols appear more promising. A variety of surgical approaches have been reported, including 360-degree anoplasty, cryosurgery, tail amputation, the débridement of necrotic tissue followed by reconstruction, or bilateral anal sacculotomy. Postoperative complications include dehiscence, fecal incontinence, and stricture formation. Positive results are reported in a

significant number of dogs when en bloc surgical resection of diseased tissue and primary wound closure were combined with bilateral anal saccullectomy and postoperative metronidazole. Using a carbon dioxide laser to surgically address perianal diseases, including fistulas, may also be a strategy for reducing postoperative morbidity.

Attempts to medically manage perianal fistula disease have included the use of prednisone (begin with 2 mg/kg q24h), cyclosporine, azathioprine, metronidazole, and topical tacrolimus ointment. A hypoallergenic or low-residue diet is often incorporated into the treatment regimen.

Azathioprine (50 mg orally [PO] q24h) and metronidazole (400 mg PO q24h) were used before surgery in a small number of dogs to effectively reduce the size and inflammation of the fistula disease. Following approximately 4 weeks of this therapy, the perianal area was surgically débrided, and the remaining anal sac tissue removed. The medications were continued, and these dogs remained disease free for at least 10 months. One potential advantage of this protocol is the cost of azathioprine and metronidazole compared to the more expensive cyclosporine.

Cyclosporine has been used as a single-agent therapy for anal furunculosis with positive results in many dogs, with treatment duration lasting up to 20 weeks and remission periods in excess of 14 months (also see Chapter 84). A starting dose of 7.5 mg/kg BID is used but adjusted based on blood trough levels 48 hours after initiating therapy. Blood levels should be somewhere between 100 to 600 ng/ml pending clinical response. The value of adjusting a patient's cyclosporine dosage based on blood levels is in question, and an alternative approach is to treat with a predetermined dosage (4 mg/kg BID to 7.5 mg/kg q24h for 13 to 24 weeks) until no further clinical improvement is observed. At that time any residual lesions may be addressed surgically. Gastrointestinal absorption of cyclosporine is improved when given with a fatty meal. Hair coat turnover, vomiting, anorexia, diarrhea, gingival hyperplasia, and papillomatosis are potential adverse effects of cyclosporine administration; and recurrence of fistula disease can be anticipated in 30% to 50% of patients. Because of the expense of cyclosporine, it is often combined with ketoconazole, which inhibits the hepatic metabolism of the drug and reduces the dose necessary to attain similar trough levels. The combination of cyclosporine (5 to 10 mg/kg BID initially with trough levels maintained above 200 ng/ml) and ketoconazole (5 to 10 mg/kg q24h) does not appear to be any more effective than cyclosporine alone but can be significantly less expensive. Remission times are similar, and recurrence should still be anticipated in at least 30% of patients.

Topical application of the immunosuppressive ointment tacrolimus (Protopic 0.1% ointment thin film applied q12-24h after gently cleaning the area) resulted in either resolution or significant improvement of perianal fistulas in a number of dogs treated for 16 weeks. The owner should wear gloves when applying the tacrolimus. Potential disadvantages of this treatment strategy include having to apply something topically to what is normally a painful area and the patient's tendency to lick at the area. Topical tacrolimus appears to be most effective in management of small lesions or as a less expensive option

following remission with cyclosporine. Treatment should continue for 4 weeks beyond clinical resolution.

Adjunct therapy involves the use of stool softeners and perianal hygiene. It is not uncommon to have fecal soiling in the perianal area, and I advise keeping the area clean and dry. Tucks Medicated Pads, topical astringent pads, are also helpful. Pain management (such as tramadol 2–5 mg/kg TID) and hot packing the area are used as needed.

Severe dyschezia secondary to perianal lesions has also been reported in dogs with cutaneous or discoid lupus erythematosus. The diagnosis is made based on histopathologic changes and therefore requires a biopsy of the area. Treatment involves immunomodulation, and response to therapy is usually good.

RECTAL DISEASE

Perineal Hernia

Perianal swelling and tenesmus are the most common presenting complaints in patients with a perineal hernia. In some animals the anatomic defect may lead to urinary bladder or prostate entrapment, and both the clinical signs and consequences quickly become more serious because of urinary obstruction. If left unattended the presence of a perineal hernia may lead to obstipation and megacolon. Perineal hernias occur most commonly in older, intact male dogs, with brachycephalic breeds predisposed to the condition. In these dogs there is an idiopathic weakening of the pelvic diaphragm. Castration appears to reduce the incidence of perineal hernias and the recurrence following surgical repair. The hormone relaxin, produced by the prostate, may be a factor in the connective tissue changes to predispose intact male dogs to herniation. Physical examination usually reveals a visible, easily reducible perineal swelling. Delineation of the defect requires a rectal examination finding a loss of the normal pelvic diaphragm laterally with a with an out pouching of the rectal wall. The herniation is generally unilateral, with the defect more commonly appearing in the right perianal region. Although it is usually rectal tissue alone that herniates, the defect may progress to include abdominal tissue such as retroperitoneal fat and/or pelvic organs such as the urinary bladder. A standard perineal herniorrhaphy, herniorrhaphy using an autogenous fascia lata graft, use of a semitendinosus muscle flap, or transposition of the internal obturator muscle has been used to surgically correct perineal hernias. In cases of bilateral herniation or in patients with prostatic disease or urinary bladder involvement, a two-step approach is used, starting with laparotomy and some combination of colopexy, vas deferens pexy, cystopexy, and prostatic omentalization. This is then followed by one of the standard surgical repair procedures. This approach appeared to be effective in a significant number of these complex cases, although urine dribbling and fecal straining were permanent conditions in a small number of dogs. Potential complications of the standard surgical repair techniques include wound infection and fecal incontinence. Recurrence following surgery appears to be rare, as does rectal prolapse or sciatic nerve injury. Urinary problems may persist

following surgery if bladder entrapment occurred with the herniation. Preoperative antibiotics to cover enteric flora are followed by postoperative lactulose to soften the stool and feeding a highly digestible, low-residue diet.

Rectal Strictures

I performed a retrospective survey of benign rectal strictures in dogs and identified 19 cases over an 8-year period (Webb, McCord, and Twedt, 2007). The vast majority of patients presented with the complaint of tenesmus, and almost all of the strictures could be identified by digital rectal examination. An underlying etiology was identified in most cases: postoperative stricture formation following surgical rectal tumor resection; the presence of foreign material (wood or bone foreign body); or stricture secondary to a chronic, severe inflammatory condition such as perianal fistula disease, histoplasmosis, anal sacculitis, or inflammatory bowel disease. My standard treatment protocol involves general anesthesia with balloon dilation of the stricture combined with intralesional injections of triamcinolone (2- to 6-mg total dose) for local antiinflammatory effects. Lesional injection can be directed with digital palpation. Some patients were also treated with a variety of other medications, including lactulose, prednisone, tylosin, or other immunosuppressive drugs.

Stricture dilation involved placement of different-diameter balloons to dilate the lumen of the stricture. Based on the size of the patient and the severity of the stricture, the diameter of balloons (generally 10 to 25 mm) and number of separate dilation sessions varied with the majority of patients. Most required one or two separate procedures performed within 7 to 10 days of each other. In general the response to this treatment protocol was good.

A rectal stricture was identified in only two cats over the same time period. In one case the stricture appeared several weeks after manual deobstipation with towel forceps in a cat with megacolon. In the other cat the stricture appeared to be secondary to inflammatory bowel disease. The cat with inflammatory bowel disease eventually did well but required multiple dilations; the other cat responded well to a treatment protocol similar to that described for the dogs.

Rectal Neoplasia

Rectal neoplasia is rare in both dogs and cats, occurring most frequently in older animals. Adenomatous polyps and adenocarcinoma represent the most common benign and malignant canine rectal tumors, respectively. Colorectal lymphoma and rectal adenocarcinoma are the rectal tumors occurring most frequently in cats, although they are uncommon. Tumors of the smooth muscle, plasmacytomas, fibromas, fibrosarcomas, and a ganglioneuroma have also been reported in the rectum of small animals.

Adenomatous rectal polyps are focal, pedunculated growths of tissue that rarely metastasize. A locally invasive and often sessile form of polyp found in the dog is referred to as a *carcinoma in situ*. Most dogs present with single, solitary masses. Despite the lack of metastasis, recurrence can be seen in up to 40% of cases, and malignant transformation of these tumors has been reported. The likelihood of recurrence and malignant transformation is greatest in

dogs that have multiple masses initially or diffuse disease and in those dogs diagnosed with carcinoma *in situ*.

The patient's presenting complaint and clinical signs are similar to those described for other forms of perianal disease, with hematochezia the most common sign, often accompanied by tenesmus and dyschezia. Anorexia, diarrhea, and weight loss may occur as the disease becomes more chronic or severe. Often the owner reports fresh bright-red blood that appears on the surface of otherwise normally formed stool toward the end of the bowel movement. Most rectal polyps and neoplasms can be palpated digitally during rectal examination, and fresh blood is frequently found on the examination glove afterwards. It is important to remember that palpation of an annular rectal ring or stricture may represent a benign response or may be primary malignant tissue. A tissue biopsy is required for a histopathologic diagnosis. Although tissue in the rectum can be obtained using a rigid proctoscopy or speculum and biopsy forceps, a more extensive examination of the colon using a flexible endoscope may better define the extent of the disease orad to the rectum or the presence of a concurrent disorder (i.e., inflammatory large bowel disease). Even with endoscopy, the mucosal biopsy may be superficial and underestimate the extent, degree, or severity of disease. Surgery is the initial treatment of choice for rectal tumors other than lymphosarcoma or plasma cell tumors. Rectal "pull-through" for the removal of a benign polyp is a relatively straightforward procedure with rare complications. Surgical removal of malignant neoplasia is more problematic, with complications that include dehiscence, infection, rectal stricture formation, or fecal incontinence. Because of this, a variety of surgical and nonsurgical treatment options continue to be explored, including radiation therapy, laser therapy, cryosurgery, electrocautery, incontinent end-on colostomy, and even piroxicam in oral or suppository forms.

Rectal Prolapse

Prolapse of the rectum, seen as a cylindric mass protruding from the anal orifice, usually results from chronic tenesmus. In dogs rectal prolapse is usually secondary to inflammation of the rectum or anus, a tumor, foreign body, perineal hernia, dystocia, proctitis, cystitis, or urethral obstruction. Rectal prolapse in the cat has been associated with chronic enteritis, dysautonomia, and rectal leiomyoma; although in most cases an etiology is not identified. Manx cats may also be predisposed to rectal prolapse. In one feline report the rectal prolapse was presumed to be secondary to tenesmus resulting from a urinary bladder transition cell carcinoma. In all cases rectal prolapse must be distinguished from the protrusion of an intestinal intussusception. In the case of rectal prolapse there is continuity between the prolapsed rectal tissue and the mucocutaneous junction of the anus. Differentiating a prolapsed intussusception from a rectal prolapse one can pass a probe in between the anus and prolapsed tissue in an intussusception.

Treatment of rectal prolapse involves removal of the underlying cause, if identified, or recurrence is highly likely. Manual reduction of a prolapsed rectum can be attempted following rehydration and reduction of the exposed edematous tissue. Water-soluble lubrication and gentle manipulation may be sufficient in some cases. Following successful

reduction a nonconstricting purse-string suture should be placed in the anus, and stool softeners and a low-residue diet should be prescribed. The purse string may remain in place for a number of weeks while the underlying primary problem is addressed. Unfortunately recurrence is seen in a significant number of cases. Surgical colopexy is then the treatment of choice for recurring rectal prolapse and has been highly effective in both dogs and cats.

CHAPTER 123

Exocrine Pancreatic Insufficiency in Dogs

MARIA WIBERG, *Helsinki, Finland*

Chronic diseases of the exocrine pancreas may affect pancreatic function and lead to inadequate production of digestive enzymes with associated maldigestion signs of exocrine pancreatic insufficiency (EPI). The exocrine pancreas has a large reserve in terms of secretory capacity, and clinical signs do not occur until about 90% of secretory capacity is lost. EPI in dogs can be the result of pancreatic acinar atrophy, chronic pancreatitis, pancreatic hypoplasia, and pancreatic neoplasia.

ETIOPATHOGENESIS

Pancreatic acinar atrophy is by far the most common reason for the clinical signs of EPI. It has been reported in many different breeds, but the breeds most commonly affected are German shepherd dogs and rough-coated collies. Recent studies suggest that in German shepherd dogs and collies pancreatic atrophy is a result of *autoimmune-mediated atrophic lymphocytic pancreatitis*, which gradually may lead to almost total destruction of pancreatic acinar tissue (Wiberg, Saari, and Westermarck, 2000). Typically

the endocrine part of the pancreas is unaffected. Genetic predisposition to the disease and the typical histologic findings during the progression of acinar atrophy have been taken as primary evidence of the autoimmune nature of the disease. In both German shepherd dogs and in collies, pedigree analyses have suggested an autosomal-recessive inheritance model. Thus far genetic studies have not been able to identify the genes involved (Moeller et al., 2002; Clark et al., 2005). Females and males usually are equally affected. Acinar atrophy is a progressive disease, as it was reported in one dog that was born with a histologically normal pancreas but developed atrophy later in life (Westermarck et al., 1993). Wiberg, Saari, and Westermarck (1999b) divided progression of acinar atrophy into a subclinical and clinical phases. The subclinical phase is characterized by marked lymphocytic inflammation into a partially atrophied acinar parenchyma. Cytotoxic T cells are predominant when the tissue destruction is in progress. When the disease progresses to end-stage atrophy, the clinical phase of EPI develops. An atrophied pancreas is thin and transparent, with no increase of fibrotic tissue.

Clinical signs of EPI usually appear at ages 1 to 5 years of age, but also can be seen in older dogs. The natural progression of the atrophic pancreatitis can vary markedly. Dogs may remain in the subclinical phase for years and sometimes for life (Wiberg and Westermarck, 2002). Markers that predict which dogs are likely to develop clinical disease or environmental factors that trigger disease have not been identified thus far.

Chronic pancreatitis is the most common cause of EPI in cats and humans. In dogs, even if chronic pancreatitis has been recognized as a cause of EPI, its prevalence and overall significance is still unclear. Unlike the situation of autoimmune atrophic pancreatitis, in chronic pancreatitis there is usually a progressive destruction of both the exocrine and endocrine pancreas accompanied by fibrosis. Clinical signs are nonspecific gastrointestinal signs and sometimes related to the development of diabetes mellitus. The congenital form of exocrine or exocrine and endocrine pancreatic hypoplasia is sometimes found in young puppies. EPI is rarely reported in association with pancreatic neoplasia.

CLINICAL SIGNS

Typical clinical signs of EPI include increased fecal volume and defecation frequency, yellow or gray feces, weight loss, and flatulence. Other common signs are polyphagia; poorly digested, loose, and pulpy feces; or coprophagia. Signs of nervousness or aggressiveness may occur possibly because of abdominal discomfort caused by increased intestinal gas. Severe watery diarrhea is usually only temporary. Skin disorders have also been reported. Although the signs of EPI are considered to be quite typical, they are not pathognomonic for pancreatic dysfunction since similar maldigestion signs may be observed in other small intestinal disorders.

DIAGNOSIS

Diagnosis of exocrine pancreatic dysfunction is based on typical clinical findings and confirmed with abnormal pancreatic function testing. Routine serum biochemistry profile and complete blood count often show unremarkable changes. Serum amylase and lipase activities are not useful in the diagnosis of EPI. Various pancreatic function tests that measure pancreatic enzymes in the blood and feces have been used in diagnosing canine EPI. The diagnostic value of the tests has relied mostly on their ability to distinguish whether the clinical maldigestion signs are caused by EPI or a disease of the small intestine.

Serum Trypsin-Like Immunoreactivity

The measurement of serum canine trypsin-like immunoreactivity (TLI) has become one of the most commonly used pancreatic function tests to diagnose canine EPI (Williams and Batt, 1988). Serum TLI measurement is both species and pancreas specific, with high sensitivity and specificity for diagnosing EPI. The reference range for canine TLI (cTLI) in healthy dogs is greater than 5.7 to 45.2 mcg/L (RIA). In dogs showing clinical maldigestion signs of EPI, cTLI concentrations are usually very low (< 2.5 mcg/L), indicating severe loss of digestive

enzyme-producing acinar tissue. However, the interpretation of cTLI values is not always straightforward. Pathologic processes affecting exocrine pancreatic function are gradually progressive, and cTLI levels can vary from normal to abnormal, depending of the degree of pancreatic tissue lost. Overlapping results between normal and affected dogs can be expected, and a normal cTLI greater than 5 mcg/L does not necessary exclude the possibility of mild-to-moderate pancreatic dysfunction. In general the lower the cTLI value, the more valuable a single measurement is in assessing the pancreatic dysfunction. Dogs with serum cTLI concentrations in the range of 2.5 to 5 mcg/L and gastrointestinal signs can be a diagnostic challenge. Whether the signs are caused by a decreased exocrine pancreatic function or disease of the small intestine may be difficult to assess, and further diagnostic procedures repeating the cTLI measurement or treatment trials are needed. In breeds predisposed to autoimmune atrophic pancreatitis, repeatedly subnormal cTLI values (2.5 to 5 mcg/L) in dogs showing no typical signs of EPI indicate subclinical EPI and suggest partial atrophy (Wiberg, Nurmi, and Westermarck, 1999a).

Fecal Enzyme Measurements

Fecal proteolytic activity measurement has been used previously for diagnosis of EPI. The problem with this test relates to the finding that at times normal dogs also show decreased proteolytic activity. To avoid this problem, fecal proteolytic activity has been measured from repeated fecal samples and after using pancreatic stimulation by giving raw soybean in the food during the test period.

Canine fecal elastase is a new species- and pancreas-specific test with high sensitivity but relatively low specificity. It has been shown that a single fecal elastase concentration greater than 20 mcg/g is valuable for excluding EPI in the dogs with chronic diarrhea. Values less than 20 mcg/g in association with typical clinical signs of EPI are suggestive of severe pancreatic dysfunction (Spillmann et al., 2000; Battersby et al., 2005).

TREATMENT

Enzyme Replacement Therapy

When clinical maldigestion signs of EPI appear, enzyme replacement therapy is indicated. Basic treatment involves supplementation of the dog's ordinary food with pancreatic enzyme extracts. Various pancreatic enzyme extracts are available. The highest enzyme activity in the duodenum has been achieved by using nonenteric-coated supplements such as powdered enzymes or raw chopped pancreas, and these supplements have proved to be equally effective in controlling clinical signs. The value of enteric-coated supplements was shown to be limited in dogs because of the delayed gastric emptying of the preparations. The maintenance dosage for the powdered enzyme depends on the preparation used (Viokase-V, Fort Dodge), 1 tsp/meal and raw frozen pancreas 50 to 100g/meal for dogs that weigh 20 to 35 kg. The use of raw pig's pancreas is prohibited in many countries because of possibilities of zoonotic diseases.

Supportive Treatments

Supportive treatments should be considered when the treatment response to enzyme replacement therapy alone is not satisfactory. Orally administered enzymes may be largely destroyed by gastric acid; and, despite accurate enzyme administration, the digestive capacity does not return to normal. In some dogs the increase of enzyme dosage or change to another nonenteric-coated supplement may be beneficial. EPI also may be associated with secondary problems that may worsen the clinical signs. These include small intestinal bacterial overgrowth, malabsorption of cobalamin, and the coexistence of a small intestinal disease.

Antibiotics

Antibiotics are the most commonly used supportive treatment. An increased amount of substrates for bacteria in the small intestine, a lack of bacteriostatic factors of the pancreatic juice, and changes in intestinal motility and immune functions are possible reasons for accumulation of bacteria in the small intestine of dogs with EPI. Antibiotics have been used during the initial treatment when clinical signs such as diarrhea, increased intestinal gas, and flatulence have not resolved with enzyme therapy or when these signs have recurred during long-term treatment. Commonly used antibiotics are tylosin (10 to 20mg/kg q12h) or metronidazole (10 to 15mg/kg q12h) for 1 to 3 weeks (Wiberg, Lautala, and Westermarck, 1998).

Dietary Modification

Clinical feeding studies during long-term treatment of EPI have shown that the need for special diets is minimal and the dogs may continue to be fed with their original diet (Wiberg, Lautala, and Westermarck, 1998; Westermarck and Wiberg, 2006). However, radical dietary changes should be avoided, and special attention should be paid to individual needs since responses to different diets varied among dogs. Furthermore, it has been shown that the severity of some clinical signs of EPI can be decreased with dietary modification. A highly digestible, low-fiber, and moderate-fat diet can alleviate clinical signs such as defecation frequency, increased fecal volume, and flatulence. Highly digestible diets may be of particular value in the initial treatment until the nutritional status has improved and possible mucosal damage has been repaired. A low-fat diet has been recommended because enzyme supplements alone are incapable of restoring normal fat absorption. Fat absorption may also be affected by bacterial deconjugation of bile salts in a small intestinal disease, producing metabolites that in turn may result in diarrhea. Dietary sensitivities may be a consequence of EPI; therefore hypoallergic diets may benefit some dogs, especially those with concurrent skin problems.

Cobalamin

Cobalamin deficiency in dogs with EPI is partly the result of increased uptake of cobalamin by intestinal bacteria

and partly because of the lack of the pancreatic intrinsic factor, shown to have a major role in the absorption of cobalamin. Because cobalamin deficiency is common in canine EPI, serum cobalamin should be measured in dogs that are clinically suspicious for EPI or do not respond satisfactorily to the enzyme treatment. Cobalamin is given subcutaneously, and the dosage currently recommended is 250 to 1000mcg once a week, depending of the size of the dog. The treatment should be repeated based on the serum levels (Ruaux, 2002).

Other Supportive Treatments

Inhibition of gastric acid secretion by H₂-antagonist may be indicated, especially when clinical signs such as vomiting or inappetence appear. Malabsorption of fat-soluble vitamins may be expected with EPI; however, the clinical importance of vitamin A, D, E, or K deficiency has not been reported. When the treatment response to enzymes and supportive therapies is still unsatisfactory, concomitant disease of the small intestine should be suspected.

Treatment of Subclinical EPI

Dogs with partial acinar atrophy but no clinical signs of EPI do not require treatment. In autoimmune atrophic pancreatitis the value of early immunosuppressive treatment in slowing the progression of the autoimmune-mediated tissue destruction was found to be questionable; thus it is not recommended (Wiberg and Westermarck, 2002).

PROGNOSIS

When the clinical signs of EPI appear, the loss of pancreatic tissue is already almost total. The changes are considered to be irreversible, and lifelong enzyme treatment is usually required. Response to enzyme treatment is usually seen during the first weeks of treatment, with weight gain, cessation of diarrhea, and decrease in fecal volume. The level of treatment response achieved during the initial treatment period seems to remain fairly stable. Although some dogs experience short relapses with associated clinical signs, the permanent deterioration of the clinical condition during long-term treatment is uncommon. During long-term treatment with nonenteric-coated enzyme supplements the gastrointestinal signs considered typical for dogs with EPI were almost completely controlled in half of the dogs (Wiberg, Lautala, and Westermarck, 1998). Although it was not always possible to eliminate all signs, acceptable resolution of signs was achieved, especially in more serious signs. Poor response to treatment was observed in 20% of the dogs despite similar treatment regimens. Furthermore about 20% of dogs diagnosed with EPI were euthanized during the first year of diagnosis. The most common reason for euthanasia was poor treatment response. Another reason was owner reluctance for expensive and lifelong treatment. A rare but severe complication of EPI is mesenteric torsion. Today mesenteric torsion is seldom seen, probably because of the more efficient enzyme preparations now available.

CHAPTER 124

Canine Pancreatic Disease

JÖRG M. STEINER, *College Station, Texas*

Pancreatitis is a common disorder in dogs, but as in humans, it is believed that the majority of cases remain undiagnosed. Mild cases of pancreatitis that do not show classical clinical signs such as vomiting and abdominal pain may be very difficult to diagnose. Moreover, the treatment of canine patients with suspected or confirmed pancreatitis remains challenging. This is in part because of the variation in severity and unpredictable course of this disease. This chapter focuses on the diagnosis and treatment of canine pancreatitis.

DIAGNOSIS

Clinical Picture

Clinical signs in dogs with pancreatitis depend on the severity of the disease. Mild cases may remain subclinical. More severe cases may present with anorexia, vomiting, weakness, abdominal pain, dehydration, and diarrhea. Severe cases can present with systemic clinical signs such as fever or even cardiovascular shock. Clinical signs in patients with pancreatitis are caused by pancreatic

inflammation or systemic effects of the pancreatic inflammation. Recent data suggest that the exocrine pancreas responds to several different noxious stimuli by a decrease in secretion of pancreatic enzymes. This is followed by the formation of giant cytoplasmic vacuoles within pancreatic acinar cells, visible only by electron microscopy. Biochemical studies have shown that these vacuoles are the product of colocalization of the zymogens of digestive enzymes and lysosomal enzymes, which are normally strictly segregated. The ensuing decrease in pH and/or the presence of the lysosomal enzymes such as cathepsin B lead to premature activation of trypsinogen. Trypsin in turn activates other zymogens, leading to local effects such as inflammation, pancreatic edema and hemorrhage, pancreatic necrosis, and parapancreatic fat necrosis. These local effects are associated with clinical signs such as vomiting and abdominal pain. Until recently it was believed that systemic signs commonly seen in pancreatitis patients, like local effects, are a direct result of circulating pancreatic enzymes. Although there is little doubt that some of these systemic effects such as systemic lipodystrophy are caused by

circulating pancreatic enzymes, recent data would suggest that other systemic sequelae are a consequence of the release of inflammatory mediators in response to pancreatic inflammation. A systemic inflammatory response consisting of release of neutrophils from the bone marrow; chemotaxis of leukocytes; degranulation of mast cells, basophils, and eosinophils; and platelet aggregation occurs commonly in patients with severe forms of pancreatitis. This response can lead to fever. Other systemic effects seen in patients with severe pancreatitis are systemic vasodilation leading to hypotension and sometimes acute renal failure, pulmonary edema leading to respiratory failure, disseminated intravascular coagulation, and in some cases multiorgan failure. Neurologic signs such as disorientation have been seen in both human and canine patients with severe pancreatitis and are sometimes referred to as pancreatic encephalopathy. Although clinical signs are not specific for pancreatitis, vomiting and cranial abdominal pain are key clinical signs in dogs with pancreatitis; and a canine patient presenting with both of these signs should be evaluated carefully for the presence of pancreatitis.

Diagnostic Tests

Complete blood count and serum chemistry profile often show mild and nonspecific changes. More severe changes can be observed in patients with severe forms of pancreatitis. Serum amylase and lipase activities are of limited clinical use for the diagnosis of pancreatitis in the dog. The specificity of both of these tests is only about 50%, even when stringent criteria are applied. Thus serum amylase and lipase activities should be used only for the preliminary diagnosis of canine pancreatitis until more definitive diagnostic tests can be performed. Radiographic changes seen in some cases include a decreased contrast in the cranial abdomen and displacement of abdominal organs. However, these changes are rather subjective, and abdominal radiography is nonspecific for canine pancreatitis. Abdominal ultrasound is useful in the diagnosis of canine pancreatitis. The sensitivity of abdominal ultrasonography in dogs is up to 68%. However, this value is largely operator dependent. Changes identified include pancreatic swelling, changes in echogenicity of the pancreas (hypoechoogenicity in cases of pancreatic necrosis and hyperechoogenicity in cases of pancreatic fibrosis) and the peripancreatic fat (hyperechoogenicity in cases of peripancreatic fat necrosis), fluid accumulation around the pancreas, and less frequently a mass effect in the area of the pancreas. Other findings that have been described are a dilated pancreatic duct or an enlarged duodenal papilla. Abdominal computed tomography is a routine procedure in humans suspected of having pancreatitis, but it appears to be very insensitive for the diagnosis of pancreatitis in veterinary species.

Trypsin-like immunoreactivity (TLI) is specific for exocrine pancreatic function. However, the sensitivity of serum canine TLI (cTLI) concentration for pancreatitis in dogs is only about 30% to 60%, making it a suboptimal diagnostic test for pancreatitis in this species. However, serum cTLI concentration remains the diagnostic test of choice for the diagnosis of EPI in dogs.

Recently an assay for measurement of canine pancreatic lipase immunoreactivity (cPLI, now measured as Spec cPL) has been developed and validated. Many different cell types in the body synthesize and secrete lipases. In contrast to catalytic assays for the measurement of lipase activity, use of immunoassays does allow for the specific measurement of lipase originating from the exocrine pancreas.

Factors that might influence cPLI have been evaluated in a number of reports. Serum cPLI was measured in a group of dogs with exocrine pancreatic insufficiency, and the median serum cPLI concentration was significantly decreased compared to that of clinically healthy dogs (Steiner et al., 2006). In addition serum cPLI concentration was nondetectable in most of the dogs, and minimal serum cPLI concentrations were observed in the rest of the dogs, indicating that serum cPLI concentration originates from the exocrine pancreas and is specific for exocrine pancreatic function. In another study serum cPLI was evaluated in dogs with experimentally induced chronic renal failure (Steiner et al., 2006). Although serum cPLI was significantly higher in dogs with experimentally induced chronic renal failure than in clinically healthy dogs, most dogs had serum cPLI concentrations within the reference range, and none of the dogs had serum cPLI concentrations that were above the currently recommended cutoff value for pancreatitis. These data suggest that the serum cPLI concentration can be used as a diagnostic test for pancreatitis even in dogs with renal failure. The long-term oral administration of prednisone has not demonstrated any effect on serum cPLI concentration. Finally, the sensitivity of different minimally invasive diagnostic tests was compared in dogs with proven pancreatitis. The sensitivity of serum TLI concentration was below 35%, and that of serum lipase activity was less than 55%. In contrast, the sensitivity for serum cPLI concentration for pancreatitis was above 80%.

Traditionally, a pancreatic biopsy has been viewed as the most definitive diagnostic tool for pancreatitis. Pancreatic biopsies can be collected during abdominal exploratory surgery or by laparoscopy. The presence of pancreatitis is easily diagnosed by gross appearance of the pancreas in many cases. However, the absence of pancreatitis can be difficult to prove. In a recent study histopathologic findings in dogs with pancreatitis were evaluated (Porterpan, Zoran, and Steiner, 2006). Pancreata were sectioned every 2 cm. In one half of all dogs with pancreatic inflammation and in two thirds of dogs with chronic pancreatitis, evidence of pancreatic inflammation was found in less than 25% of all sections. Thus, even if multiple biopsies are collected, pancreatic inflammation, especially in cases of chronic pancreatitis, may easily be missed. It should also be noted that, although a pancreatic biopsy in itself is not associated with many complications, many patients with pancreatitis are poor anesthetic risks.

TREATMENT OF SEVERE PANCREATITIS

Severe pancreatitis is characterized by extensive pancreatic necrosis and systemic complications and is often associated with a poor prognosis. Severe pancreatitis can

occur in patients with acute disease or as an exacerbation of chronic pancreatitis.

Removal of Inciting Cause

Unfortunately the cause remains unknown in many dogs with pancreatitis. However, every possible effort should be made to identify a cause and remove it. Several causes and risk factors have been identified for pancreatitis in dogs (Hess et al., 1998).

Nutrition

There is much anecdotal but little scientific evidence that a fatty meal causes pancreatitis. Thus dogs with pancreatitis should be evaluated for the presence of hypertriglyceridemia. If hypertriglyceridemia is present, it may either be the cause or an effect of pancreatitis. Regardless, measures should be taken to decrease serum triglyceride concentrations, initially by placing the patient on a low-fat diet or, if dietary management alone is insufficient in controlling hypertriglyceridemia, by also adding gemfibrozil or other lipid binders to the diet. It may be prudent to switch pancreatitis patients to a low-fat diet even if they do not have hypertriglyceridemia.

Toxins and Drugs

Many drugs and drug classes have been implicated in causing pancreatitis in humans. However, definitive proof of a cause-and-effect relationship is extremely rare. Drugs that have been implicated in causing pancreatitis in humans that are also used in veterinary medicine include calcium, potassium bromide, L-asparaginase, azathioprine, estrogen, organophosphates, and some less commonly used drugs. Corticosteroids do not appear to cause pancreatitis, although they can increase serum lipase activity in dogs without causing pancreatitis.

Trauma and Hypoperfusion

Several cases of pancreatitis after traffic accidents and similar traumatic injuries have been reported. Surgical trauma has also been implicated as a cause of pancreatitis. However, evidence from the human literature, as well as experimental data, would suggest that hypoperfusion of the gland secondary to hypotensive states such as may occur during anesthesia rather than trauma to the pancreas per se is responsible for pancreatitis in the majority of postsurgical cases of canine pancreatitis.

Other Causes

Hypercalcemia has been shown to cause pancreatitis in several species and should be corrected by appropriate management when identified. Pancreatitis can also occur in association with neoplastic infiltration by pancreatic adenocarcinoma.

Supportive Care

Aggressive fluid therapy is the mainstay of treatment for pancreatitis and must be individualized, depending on the needs of the patient. The fluid rate chosen depends on the estimated degree of dehydration, the estimated ongoing fluid losses, and the calculated daily maintenance

rate. Careful attention to maintenance of a normal serum potassium concentration is particularly important because anorectic, vomiting patients with pancreatitis are particularly prone to hypokalemia. Although hypocalcemia is often noted, it is usually mild, and calcium supplementation should be reserved for the rare animals that manifest clinical signs in association with serum calcium concentrations less than 6.5 mg/dl. Acid-base imbalances are common in dogs with pancreatitis. Since either acidemia (most common) or alkalemia may develop, blind correction of suspected acid-base imbalance should not be attempted. Arterial blood pH, P_{CO_2} , and bicarbonate should be measured in patients with severe pancreatitis whenever possible.

Metabolic Support

It is still common practice to give nothing orally to patients with pancreatitis. This recommendation is sensible in patients that are vomiting. However, the importance of this therapeutic strategy remains scientifically unproven. I currently recommend withholding food and water only from patients that vomit and only for a maximum period of 2 to 4 days. When vomiting ceases, small amounts of water can be offered several times per day. If vomiting does not recur, small amounts of a diet that is low in fat and moderate in protein content (rice, pasta, potatoes, or a commercial diet) can be given. If vomiting does not subside and oral feeding is withheld for more than 2 to 4 days, the nutritional needs of the patient have to be met by alternative metabolic support such as jejunostomy tube or total or partial parenteral nutrition (see Chapter 3 and Section VI on Evolve).

Symptomatic Therapy

Analgesic Therapy

Many patients with pancreatitis do not show overt signs of abdominal pain. Regardless of clinical signs, patients with pancreatitis should be assumed to have abdominal pain and should be treated accordingly. There are many possible choices for antianalgesic therapy, including many opioids or lidocaine (see Chapter 2). Lidocaine can be added to the analgesic protocol by the intravenous or intraperitoneal route.

Antiemetics

The use of antiemetics used to be controversial. Metoclopramide was one of the most commonly used antiemetic agents. However, metoclopramide is a dopamine antagonist, and pancreatic blood flow is regulated via dopaminergic receptors. The advent of new antiemetics has dramatically changed the therapy of patients with pancreatitis. Dolasetron (Anzemet, given at 0.3 to 0.6 mg/kg once to twice daily IV, SQ, or PO) is a 5HT antagonist and a very potent antiemetic with few side effects. In many patients vomiting can be stopped altogether after therapy with dolasetron has been instituted. Another newer veterinary antiemetic, maropitant (Cerenia, Pfizer) given at 1 mg/kg once daily SQ, is a neurokinin 1 (NK1) antagonist with broad spectrum action and appears to be very effective in the management of vomiting from pancreatitis.

Plasma Therapy

α_2 -Macroglobulin, one of the scavenger proteins for activated proteases in plasma, is depleted rapidly in severe pancreatitis, with resultant uninhibited protease activity leading to acute disseminated intravascular coagulation, hypotensive shock, and death. Fresh frozen plasma not only replenishes α_2 -macroglobulin but also supplies albumin and coagulation factors, which have several beneficial effects, including maintaining plasma oncotic pressure and preventing disseminated intravascular coagulation. Although there is no scientific evidence that plasma has beneficial effects in either human or canine patients with severe pancreatitis, I routinely give fresh frozen plasma (50 to 250ml once a day) to patients with severe pancreatitis.

Antibiotic Therapy

There has been much debate about the use of antibiotics in humans with pancreatitis. Evidence is limited that humans with pancreatitis benefit from prophylactic antibiotic use, even though nearly 50% of all patients with fatal pancreatitis die of an infectious complication. Dogs with pancreatitis rarely have infectious complications; thus there is no evidence to support routine antibiotic therapy in canine patients with pancreatitis. Furthermore, inappropriate antibiotic therapy may increase the risk of antibiotic-resistant infections. If an infectious complication is suspected, efforts should be made to identify the causative organism before initiating treatment with an appropriate broad-spectrum antibiotic agent.

Other Treatment Strategies

Antiinflammatory Drugs

There is no evidence to support the use of corticosteroids or nonsteroidal antiinflammatory drugs in the treatment of canine pancreatitis. Treatment with corticosteroids should be reserved for use in cases of severe shock and should be used only for a short time in concert with other aggressive supportive measures.

Protease Inhibitors

Initial experimental data in dogs showed a benefit of protease inhibitors such as aprotinin in canine pancreatitis. However, clinical trials in humans led to disappointing results; and, given the new information concerning the pathogenesis of severe pancreatitis, this is not surprising. Once premature activation of pancreatic zymogens has occurred, a massive inflammatory response follows that is mediated by inflammatory cytokines. At that point further premature activation of pancreatic zymogens probably plays a very minor role in the progression of the disease; thus inhibition of pancreatic enzymes would not confer any medical benefit.

Antioxidants

Over the last two decades multiple studies have evaluated the use of antioxidants in humans with pancreatitis. Some noncontrolled studies found a benefit, whereas con-

trolled studies did not identify any benefit of selenium or other antioxidants. Only one report is available about the use of antioxidants in dogs with pancreatitis. In this study the authors showed a significantly decreased mortality rate in dogs treated with standard care and selenium when compared to dogs treated with standard care alone. Unfortunately the control reference group consisted of historic control dogs, thus the results of this study leave many questions.

Miscellaneous Treatment Strategies

Many other treatment strategies have been evaluated in human or veterinary patients with pancreatitis. Antisecretory agents such as anticholinergics, calcitonin, or glucagon have all failed to show any beneficial effect in humans with pancreatitis and have not been evaluated systematically in dogs. Nasogastric suctioning and inhibition of gastric acid secretion also have not proved effective in human patients. Somatostatin has shown promise in reducing complications in humans with pancreatitis, but in some recent experimental studies in rats somatostatin administration led to deterioration of the experimental pancreatitis. Surgical management of pancreatitis has become uncommon in humans with pancreatitis. This is mainly because surgical management is not associated with improved outcome and many patients with acute pancreatitis are poor surgical risks.

TREATMENT OF MILD PANCREATITIS

Mild pancreatitis is associated with minimal pancreatic necrosis and few systemic effects and is usually followed by complete recovery. It is likely that many animals recover spontaneously without medical intervention after a few days of mild depression and inappetence. However, some animals present with repeated signs of vomiting, abdominal discomfort, and depression, with evidence of either recurrent acute or chronic pancreatitis. Such animals may ultimately develop diabetes mellitus or exocrine pancreatic insufficiency if enough pancreatic tissue has been destroyed. Unfortunately little is known about treatment of mild chronic pancreatitis and prevention of progression toward end-stage disease. As with acute pancreatitis, an effort should be made to identify the cause and rectify it if possible. Miniature schnauzers commonly exhibit hypertriglyceridemia. If serum triglyceride concentrations are increased, feeding a low-fat diet may help reduce triglyceride concentrations and improve clinical signs. Chronic abdominal pain is one of the most important problems in humans with chronic pancreatitis and may affect some canine patients as well. If pain is suspected, the animal can be given 0.5 to 2 tsp of dried pancreatic extract (Viokase; or Pancrezyme, Virbac) with each meal on a trial basis. Although these patients do not have exocrine pancreatic insufficiency and do not require enzyme replacement for digestive purposes, the feedback effect of digestive proteases within the gut lumen appears to reduce the drive on pancreatic secretion and perhaps reduce the pancreatitis-associated discomfort. Patients with chronic mild pancreatitis should also be evaluated for concurrent conditions such as inflammatory bowel disease, hepatitis, and diabetes mellitus.

Over the last decade the frequency of a diagnosis of autoimmune pancreatitis has increased dramatically in humans. Although autoimmune pancreatitis has not been diagnosed definitively in dogs, many dogs with chronic pancreatitis show a lymphocytic infiltration of the exocrine pancreas. Thus I have cautiously attempted treatment of mild chronic pancreatitis with glucocorticoids in cases that do not improve with a low-fat diet alone and do not have any concurrent diseases.

CHAPTER 125

Feline Exocrine Pancreatic Disease

DAVID A. WILLIAMS, *Urbana, Illinois*

The incidence of exocrine pancreatic disorders has traditionally been considered to be low in the cat. However, a large retrospective study of necropsy findings showed 1.3% of 6504 feline pancreata to have pathologically significant lesions. In contrast, of 180,648 cats entered into the Veterinary Medical Data Base over a 10-year period, only 1027 (0.57%) were diagnosed with exocrine pancreatic disorders. Thus it appears that, although cats suffer from diseases of the exocrine pancreas quite frequently, these disorders often escape diagnosis.

PANCREATITIS

Classification

A simple classification system for pancreatitis has been established for human patients (Bradley, 1993), and, since no such system has been devised for veterinary medicine, the human classification system is applied when possible. Acute pancreatitis is an inflammatory condition of the pancreas, which is completely reversible after removal of the inciting cause. In contrast, chronic pancreatitis is characterized by irreversible histopathologic changes of exocrine pancreatic tissue, most notably fibrosis and atrophy. Both forms can be mild or severe. Mild forms of pancreatitis are associated with little or no pancreatic necrosis or systemic effects, and usually

complete recovery is possible. In contrast, severe forms of pancreatitis are associated with extensive pancreatic necrosis and multiple organ involvement and often have a poor prognosis. Chronic forms of pancreatitis appear to be more common than the acute form in cats, whereas in dogs the diagnosis of chronic pancreatitis is uncommon.

Etiology and Pathogenesis

Extensive studies of experimental pancreatitis in cats and other species have led to the generally accepted hypothesis that pancreatic acinar cells ultimately respond in a common fashion to a variety of differing harmful stimuli. Briefly an initial decrease in secretion of pancreatic enzymes is followed by formation of abnormal cytoplasmic vacuoles in which the contents of lysosomes and zymogen granules colocalize. This leads to an inappropriate intracellular activation of trypsin and subsequently other digestive zymogens. These activated digestive enzymes lead to local effects, including inflammation, hemorrhage, acinar cell necrosis, and peripancreatic fat necrosis. Digestive enzymes released into the bloodstream may cause systemic effects, including systemic inflammatory changes, systemic vasodilation leading to hypotension, pulmonary edema, disseminated intravascular coagulation, central neurologic deficits, respiratory failure, renal failure, and even multiorgan failure.

Several diseases and risk factors have been associated with feline pancreatitis. Traumatic pancreatitis (caused by road traffic accidents or falling from heights) has been reported and probably develops secondary to pancreatic ischemia rather than from trauma per se. Infectious agents have been shown to cause feline pancreatitis, with the strongest evidence for a causal relationship for *Toxoplasma gondii* and rare cases of *Amphimerus pseudofelineus* fluke infestation. Weaker evidence has been presented for feline parvovirus infections in kittens, and infections with feline herpesvirus-II and feline infectious peritonitis virus. Feline pancreatitis has been reported subsequent to topical use of fenthion, an organophosphate cholinesterase inhibitor. Many other pharmaceutical compounds have been implicated in causing pancreatitis in humans and dogs (including azathioprine, chlorothiazide, hydrochlorothiazide, estrogens, furosemide, tetracycline, sulfonamides, L-asparaginase, 6-mercaptopurine, methyl dopa, pentamidine, nitrofurantoin, dideoxyinosine, valproic acid, and procainamide). However, no cases have yet been reported in the cat. Cholangitis and cholangiohepatitis may also coexist in feline patients with pancreatitis, but the significance of this relationship is unknown. Most cases of feline pancreatitis are idiopathic.

Clinical Picture and Diagnosis

Clinical signs of cats with pancreatitis are nonspecific. In one report of 40 cats with severe pancreatitis lethargy was reported in 100% of the cases, anorexia in 97%, dehydration in 92%, hypothermia in 68%, vomiting in 35%, abdominal pain in 25%, a palpable abdominal mass in 23%, dyspnea in 20%, ataxia in 15%, and diarrhea in 15% (Hill and Van Winkle, 1993). Especially remarkable is the low incidence of vomiting and abdominal pain, both of which are common clinical signs in human and canine patients with severe pancreatitis. Other clinical signs, such as polyphagia, constipation, fever, icterus, polyuria, polydipsia, and adipsia have also been reported. Concurrent conditions occur frequently, including hepatic lipidosis, inflammatory bowel disease, interstitial nephritis, diabetes mellitus, and cholangiohepatitis (Akol et al., 1993). Clinical signs in less severe cases are not documented, but many cases are associated with very vague signs such as poor body condition, and some cases can be subclinical.

Complete blood count and serum chemistry profile often show mild and nonspecific changes. Serum activities of lipase and amylase are within the reference ranges in most cases, and both tests are considered unreliable for the diagnosis of pancreatitis in the cat. Typical radiographic changes seen in some cases may include decreased contrast in the cranial abdomen with displacement of the duodenum laterally and dorsally, the stomach to the left, and the transverse colon caudally. Abdominal ultrasound is considered more useful in the diagnosis of feline pancreatitis than radiographs. Changes identified include pancreatic swelling, increased echogenicity of the pancreas, fluid accumulation around the pancreas, and less frequently a mass effect in the area of the pancreas. Abdominal computed tomography is reported to have low sensitivity (approx 33%) for detecting feline pancreatitis and is rarely used.

Immunoassay of serum feline trypsin-like immunoreactivity (fTLI) and more recently feline serum pancreatic lipase immunoreactivity (fPLI), currently only available through my former laboratory at Texas A&M University (the gastrointestinal laboratory), have both been evaluated as a diagnostic tool for feline pancreatitis. Available evidence found an increase in serum fTLI and fPLI in many cats with pancreatitis (Steiner and Williams, 1996). Subsequent studies in cats with experimental mild transient pancreatitis indicate that increases in serum fTLI, while often dramatic, are transient and return to normal within 2 to 3 days; whereas increases in serum fPLI in the same cats are far more prolonged, usually persisting for at least 7 to 10 days. Consequently fPLI appears to be a better clinical diagnostic test for acute and chronic pancreatitis in the cat, but large clinical studies are required to better support this observation.

A definitive diagnosis of feline pancreatitis may be made by examination of pancreatic biopsy samples obtained at exploratory laparotomy or laparoscopy. Several areas should be sampled because lesions often have a patchy distribution. Although pancreatic biopsy per se is safe, this intervention is obviously relatively expensive and may be contraindicated in some patients because of high anesthetic risk.

Therapy

Supportive Therapy

Whenever possible the inciting cause should be removed. Exposure to unnecessary drugs, especially those implicated in causing pancreatitis, should always be avoided. Aggressive fluid therapy is the mainstay of supportive therapy for acute pancreatitis and helps reverse and minimize pancreatic ischemia. Fluid, electrolyte, and acid-base imbalances need to be assessed and corrected as soon as possible. Plasma transfusions should be considered in any patients exhibiting severe clinical signs and in those with hypoalbuminemia.

Alimentation

The traditional recommendation for any patient with pancreatitis is to feed nothing by mouth for several days. This recommendation is justified in patients that vomit, but there is little evidence to substantiate this strategy in cats that will eat and do not vomit. This issue is complicated further by the fact that cats with pancreatitis may have concurrent hepatic lipidosis (Akol et al., 1993). Current clinical experience indicates that the benefit of nutritional support for cats with hepatic lipidosis overrides the conventional dogma that food should be withheld from patients with pancreatitis. Reassuringly, recent studies have failed to show any harmful effects resulting from feeding humans with pancreatitis. Theoretically the preferred route of alimentation is via a jejunostomy tube, but this is impractical in many cases; and both gastrostomy and nasogastric tubes appear to be well-tolerated alternatives, providing that the patient does not vomit. Cats do not seem to benefit from feeding of a specially formulated low-fat diet, and commercially available feline liquid diets appear to be well tolerated despite their high fat contents. If there is no evidence to support concurrent hepatic lipidosis, cats should probably be held NPO for

3 to 4 days, especially if they are vomiting frequently. After this time oral water is slowly reintroduced, followed by trial feeding of small meals.

Analgesia

Even though abdominal pain is rarely appreciated in cats with pancreatitis, it is probably present frequently and may be a major contributing cause of anorexia. Routine analgesic administration is warranted in most patients with acute disease. Historical concerns that some analgesics such as morphine may exacerbate pancreatitis are now discounted, and any of the agents currently used in cats is suitable for use. Meperidine (Demerol HCl, Winthrop-Breon) at a dosage of 1 to 2 mg/kg every 2 to 4 hours can be given intramuscularly or subcutaneously. Butorphenol tartrate (Torbutrol or Torbugesic, Fort Dodge) at a dosage of 0.2 to 0.4 mg/kg every 6 hours subcutaneously can also be used, but there are also many other alternatives (see Chapter 2).

Plasma

Studies in dogs show that, when α_2 -macroglobulin, one of the scavenger proteins for activated proteases in serum, is depleted, death ensues rapidly. Fresh frozen plasma (FFP) or fresh whole blood contains not only α_2 -macroglobulin, but also albumin, which has many beneficial effects in patients with experimental pancreatitis. Clinical trials in humans have not shown enhanced survival, but, because of my experience and anecdotal reports of beneficial effects of FFP in canine patients with pancreatitis, I recommend the use of FFP or fresh whole blood in cats with severe acute pancreatitis.

Antibiotic Therapy

There is no evidence to recommend the routine use of antibiotic agents in cats with acute pancreatitis. Infectious complications of feline acute pancreatitis are very rare and are usually not the cause of death in fatal cases. Antibiotic therapy should be reserved for patients with known or suspected concurrent infectious diseases or complications such as infected catheters, and these patients should be treated aggressively after appropriate antibiotic sensitivity testing of the causative agent.

Cats having acute neutrophilic (suppurative) cholangitis, thought to be the result of an ascending bacterial infection of the biliary system, may also have a concurrent bacterial infection in the pancreatic duct system because of the direct communication of the common bile duct and pancreatic ducts in the cat. In these cases antibiotic therapy directed against enteric aerobes would be indicated.

Antiinflammatory Agents

There are no data on the use of antiinflammatory agents in cats with severe pancreatitis, and no benefit was found in humans. In cats having severe acute pancreatitis corticosteroids should only be used in cases of secondary cardiovascular shock. However, corticosteroids may be helpful when treating cats with chronic pancreatitis and concurrent inflammatory bowel disease or cholangitis. Corticosteroid therapy does not appear to have any adverse consequences, and improvement of clinical signs together with reductions in serum fTLI and fPLI are noted frequently.

Dopamine

Dopamine has been shown to have beneficial effects in experimental cases of feline acute pancreatitis when given in the first 12 hours after induction, but there was no beneficial effect when given after 12 hours. In addition, dopamine must be used carefully in patients with cardiac arrhythmias and may also cause nausea and vomiting. Therefore it cannot be recommended for routine use in feline patients with pancreatitis but may be of value in selected cases.

Other Therapeutic Strategies

Many other therapeutic strategies such as the administration of trypsin-inhibitors (e.g., Trasylol [recently taken off the market]), antacids, antisecretory agents (i.e., anticholinergics, calcitonin, glucagon, somatostatin), or selenium, as well as peritoneal lavage, have been evaluated in human and canine patients suffering from pancreatitis. None of these strategies has shown any beneficial effect at this point and therefore cannot be recommended until evidence for their usefulness is forthcoming.

It should also be remembered that many cats suffer from mild forms of chronic pancreatitis, which is almost certainly a distinct entity from severe acute pancreatitis. These cats often suffer from concurrent conditions, most notably inflammatory bowel disease, cholangitis, or both and, as mentioned previously, may benefit from corticosteroid therapy directed primarily to treat the intestinal or liver disease. In many of these cats the pancreatitis may be relatively or completely subclinical. Some cats with persistent elevations in pancreatic marker enzymes (fTLI and fPLI) often do not do as well as cats in which values decrease or become normal during therapy. This may reflect the persistence of clinically significant pancreatitis in these individuals, and unfortunately very little is known about appropriate therapy for these patients if corticosteroids are ineffective. Treatment should be directed at any concurrent conditions in the hope that the pancreatitis component is of minimal clinical significance, which in many patients appears to be the case, since they can do very well despite persistence of mild-to-severe increases in serum fTLI and fPLI.

Prognosis

The prognosis for cats suffering from severe acute pancreatitis depends on the severity of the disease, the extent of pancreatic necrosis, the occurrence of systemic and pancreatic complications, the duration of the condition, and the presence of concurrent disease. The prognosis for chronic pancreatitis is certainly better; in some cases the disease can be subclinical, and some cases respond positively to corticosteroid therapy given primarily to treat concurrent inflammatory bowel disease. In the long term some patients with chronic disease may develop diabetes mellitus and/or exocrine pancreatic insufficiency (EPI) if sufficient pancreatic tissue is irreversibly destroyed.

EXOCRINE PANCREATIC INSUFFICIENCY

EPI is a syndrome that is caused by insufficient synthesis and secretion of digestive enzymes by the exocrine

portion of the pancreas, leading to insufficient activity of digestive enzymes in the lumen of the small intestine (Williams, 1994).

Etiology and Pathogenesis

As in humans, chronic pancreatitis is the most common cause of EPI in the cat, although pancreatic acinar atrophy resembling that seen in dogs also occurs. A rare cause is infestation with the fluke *Eurytrema procyonis*.

Almost all of the functional capacity of the exocrine portion of the pancreas must be lost before clinical signs develop. The lack of digestive enzymes in the duodenum leads to maldigestion, but secondary disturbances of intestinal mucosal transport mechanisms also contribute to nutrient malabsorption. These changes lead to variable diarrhea, weight loss, and malabsorption of selected nutrients, including cobalamin and some fat-soluble vitamins.

Clinical Picture and Diagnosis

Cats with EPI often present with a chronic history of polyphagia, diarrhea, and weight loss, each of which can vary markedly in severity. The hair coat can appear greasy, especially in the perineal and tail region, as a consequence of steatorrhea. The remainder of the hair coat can have an unkempt and wet appearance related to cobalamin deficiency. Results of a complete blood count, serum chemistry profile, and urinalysis are within the reference ranges in most cases; and there are no abnormalities on abdominal radiographic and ultrasonographic examination. The most reliable test for the diagnosis of EPI in the cat is radioimmunoassay of serum fTLI (Steiner, Medinger, and Williams, 1996), which reveals markedly subnormal values in affected cats (Steiner and Williams, 1996). Cats with EPI almost always have severely reduced serum cobalamin concentrations and less frequently folate concentrations. Therefore serum cobalamin and folate concentrations should be determined in all cats with suspected EPI.

Management

Pancreatic Enzyme Supplementation

Pancreatic enzyme supplementation using dried powdered extracts of porcine or bovine pancreas is the mainstay of therapy for cats with EPI. Initially ½ to 1 teaspoonful should be mixed into each meal immediately before feeding. It is rare for cats with EPI to refuse treated food; but, if this is a problem, the enzymes can be packed into gelatin capsules or raw pork or beef, or other pancreas can be given. Pancreas can be stored frozen for many months without losing activity, and 1 to 3 oz (30 to 90 g) of chopped raw pancreas is given per meal initially. Tablets, capsules, and enteric-coated products should be avoided. Preincubation of the food with pancreatic enzymes, supplementation with bile salts, or concurrent antacid therapy is unnecessary. Once clinical signs have resolved, the dose of pancreas extract can be decreased gradually until a minimal effective dose is determined. This dose differs among patients and may also change with different batches of the pancreatic supplement.

Dietary Considerations

There are no studies of the effect of differing diets on feline patients with EPI, and most cats do well on any high-quality commercial maintenance diet. Low-fat diets should be avoided because of their lower calorie density, as should diets containing unusually high amounts of fiber because some types of dietary fiber interfere with pancreatic enzyme activity. Unless an individual patient has a suboptimal response, routine feeding of a special diet is not necessary.

Vitamin Supplementation

Most cats with EPI are severely cobalamin deficient. Some of these cats do not respond well to enzyme supplementation until cobalamin is also supplemented. Initially 250 mcg of cobalamin (cyanocobalamin injection, Elkins-Sinn, Goldline, or others) are given subcutaneously once a week. The serum concentration of cobalamin should be rechecked immediately before the fifth or sixth injection. If serum cobalamin concentration has normalized, the dosing schedule can be changed to monthly maintenance injections. Although this prevents recurrence of deficiency, some owners report that their cats do better when receiving injections every 1 to 2 weeks. Supplementation is required for life; otherwise cobalamin deficiency will recur. Cats with subnormal serum folate should be treated with 200 mcg of folic acid daily added to the food for 1 month. The risk of recurrence of deficiency once folate supplementation is stopped is not known; thus serum folate should be retested at least annually. Deficiencies of fat soluble-vitamins are uncommon but have been reported and should be anticipated as potential complications. Vitamin K deficiency can lead to death from acute gastrointestinal hemorrhage, but patients at risk can be identified by evaluation of prothrombin and activated partial thromboplastin times, and deficiency is reversed by appropriate supplementation with vitamin K injections. Vitamin E deficiency may contribute to neurologic abnormalities and retinal atrophy and can be overcome by supplementation of the diet with 30 units of tocopherol daily.

Treatment of Concurrent Conditions

Some cats with EPI do not respond appropriately to enzyme and vitamin supplementation. Many of these cats have concurrent small intestinal disease (as often indicated by observation of subnormal serum folate concentration) and must be evaluated and treated appropriately for villous atrophy and inflammatory bowel disease. Finally some cats with EPI suffer from concurrent diabetes mellitus and must be managed accordingly.

Prognosis

EPI is associated with irreversible loss of pancreatic acinar tissue in most cases; therefore recovery is improbable. However, with appropriate management and monitoring these patients usually become clinically normal and should enjoy a normal life span.

EXOCRINE PANCREATIC NEOPLASIA

Pancreatic adenomas are benign tumors of the exocrine pancreas, whereas pancreatic adenocarcinoma is the most

common malignant neoplastic condition of the exocrine pancreas in the cat (Andrews, 1987). Spindle cell sarcoma and lymphosarcoma have also been reported in feline patients.

Pathogenesis

Pancreatic adenomas are usually subclinical but, if large, may lead to clinical signs because of the transposition of other abdominal organs. Pancreatic adenocarcinomas can also lead to signs of EPI related to obstruction of the pancreatic duct and acinar atrophy or pancreatitis related to either tumor necrosis and/or local pancreatic ischemia. Metastatic disease may lead to clinical signs related to dysfunction of other organs.

Clinical Signs and Diagnosis

The presenting clinical signs of feline patients with exocrine pancreatic neoplasia are nonspecific. In a case series of 58 cases, clinical signs most commonly reported were anorexia, weight loss, lethargy, and vomiting (Andrews, 1987). Clinical signs reported in other cases are icterus, constipation, diarrhea, polyuria, fever, dehydration, and distended cranial abdomen. Finally, some reported clinical signs that are related to metastatic lesions, may include dyspnea, lameness, bone pain, or alopecia.

Results of routine blood tests are usually unremarkable. Serum lipase and amylase activities have been reported in few cases and have rarely been elevated. Radiographic findings are also nonspecific in most cases, but ultrasonographic examination of the abdomen is often very helpful, revealing a soft-tissue mass in the region of the pancreas. Even though most pancreatic adenocarcinomas exfoliate poorly into the peritoneal fluid, peritoneal effusion, if present, should be aspirated and evaluated cytologically. Tissue sampling by either fine-needle aspiration or transcutaneous biopsy under ultrasound guidance can be attempted when masses are identified, but in many cases definitive diagnosis is made at exploratory laparotomy or necropsy.

Therapy and Prognosis

Pancreatic adenomas are benign and theoretically do not need to be treated unless they are causing clinical signs. However, the final distinction between pancreatic adenoma and adenocarcinoma is often made at exploratory laparotomy, and a partial pancreatectomy should be performed at that time, even in cases of suspected pancreatic adenoma. The prognosis for pancreatic adenoma is excellent.

Pancreatic adenocarcinomas usually present at a late stage of the disease, and metastasis has been reported to occur in more than 80% of cats at the time of diagnosis. In the few cases when metastatic lesions are not identified at the time of diagnosis, surgical resection can be attempted. However, owners should be forewarned that clean surgical margins are rare. Total pancreatectomy and pancreaticoduodenectomy, although theoretically possible, have not been described in cats; and, given experiences in experimental animals and humans, both high morbidity and mortality are likely. Further the expense and complexity of lifelong management of concurrent postsurgical EPI and

diabetes mellitus would make this option unacceptable for many owners. Chemotherapy and radiation therapy have shown little success in humans or veterinary patients with pancreatic adenocarcinomas. Overall the prognosis for cats with pancreatic adenocarcinoma is grave.

PANCREATIC BLADDER

A pancreatic bladder is an abnormal extension of the pancreatic duct, forming a sac. Only a few feline cases have been described in the literature. These cats presented with clinical signs compatible with biliary duct obstruction. Many cases are probably subclinical. Optimum management has not been described, but surgical reconstruction may be most suitable in cats presenting with clinical signs.

PANCREATIC PSEUDOCYST

Pancreatic pseudocyst, a collection of sterile pancreatic juice enclosed by fibrous or granulation tissue, is a recognized complication of pancreatitis in humans and has recently been reported in a cat (Hines et al., 1996). Clinical signs observed in the cat were similar to those in cats with pancreatitis. Abdominal ultrasound revealed a cystic structure in close proximity to the left lobe of the pancreas. Pancreatic pseudocysts in humans are treated by surgical correction when they enlarge or do not regress. Surgical intervention was also successful in the management of the cat reported.

PANCREATIC ABSCESS

A pancreatic abscess is a collection of pus with little or no pancreatic necrosis, most commonly in close proximity to the pancreas. Pancreatic abscess has been described as a complication of pancreatitis in humans and dogs but not in the cat. However, I am aware of one feline patient with pancreatic abscess confirmed by histopathology. Surgical intervention and aggressive antibiotic therapy are the treatments of choice in humans and dogs with pancreatic abscess and were successful in treating this cat.

PANCREATIC PARASITES

Eurytrema Procyonis

The pancreatic fluke of the cat, *Eurytrema procyonis*, has been found in pancreatic ducts of cats, foxes, and raccoons. The parasites can lead to ductular thickening and fibrosis of acinar tissue. A significant decrease of pancreatic secretions has been shown in some cases. However, clinical signs of EPI in cats with *E. procyonis* are rare. Diagnosis is made by identification of eggs in fresh feces. Fenbendazole (Panacur, Hoechst) at a dosage of 30mg/kg orally once a day for 9 days has been recommended for therapy.

Amphimerus Pseudofelineus

The hepatic fluke of the cat, *Amphimerus pseudofelineus*, can also invade the pancreas and cause pancreatitis. Etiologic diagnosis is possible by identification of eggs on

fecal examination by formalin-ethyl acetate sedimentation. In one clinical report treatment with praziquantel (Droncit, Miles), 40mg/kg orally once daily for 3 consecutive days was successful.

CHAPTER 126

Diagnostic Approach to Hepatobiliary Disease

CYNTHIA R.L. WEBSTER, Grafton, Massachusetts
JOHANNA C. COOPER, Plymouth, Massachusetts

Diagnosing primary hepatobiliary disease in small animals is often a challenge. The clinical signs of hepatobiliary disease generally reflect deficiencies in the varied functions of the liver. These diverse metabolic and biochemical activities include carbohydrate, lipid, and protein metabolism; fat digestion; detoxification of endogenous and exogenous substances; and immune surveillance. However, the clinical signs that develop with liver disease are seldom specific for that organ. Furthermore, the high blood flow of the liver, its dual blood supply (systemic and portal), and its role in detoxification render the liver sensitive to injury from both systemic disorders and diseases in organs drained by the portal circulation (Box 126-1). To complicate the situation, the tremendous hepatic reserve capacity almost assures that relatively specific signs of hepatobiliary dysfunction such as icterus, hypoglycemia, bleeding tendencies, hepatic encephalopathy (HE), and ascites occur only in late-stage disease. The purpose of this chapter is to provide a rational approach to the diagnosis of hepatobiliary disease in small animal patients.

The first step in the diagnosis of hepatobiliary disease is to obtain an accurate history. Pertinent information includes the use of potentially hepatotoxic drugs, supplements, or nutraceuticals; exposure to environmental toxins, infectious agents, or recent anesthetic events; and details on housing, supervision outdoors, and travel and vaccine status (leptospirosis, canine adenovirus). Recognition of an agent's hepatotoxic potential (Box 126-2) and prompt withdrawal can prevent further liver damage. Often a sequence of events may increase the suspicion for hepatobiliary disease. A history of inappetence and weight loss in a previously overconditioned feline is suggestive of hepatic lipidosis. Anesthetic intolerance, failure to thrive, and postprandial behavioral abnormalities in a predisposed canine breed should increase one's suspicion of a portosystemic vascular anomaly (PSVA) (Box 126-3). Primary hepatobiliary disease should always be considered in breeds predisposed to inflammatory/fibrotic hepatopathies (see Box 126-3).

Patients with hepatobiliary disease may exhibit non-specific clinical signs referable to the gastrointestinal (intermittent anorexia, vomiting, diarrhea, and/or weight

loss), urinary (polyuria, polydipsia, stranguria, and dysuria), or central nervous systems (lethargy and depression). More specific signs of hepatobiliary disease include the diffuse cerebral signs that accompany HE (blindness, head pressing, stupor, coma, and ptyalism [cats]), jaundice, bleeding tendencies, or dermatologic abnormalities (superficial necrolytic dermatitis).

Physical examination in patients with primary hepatobiliary disease may reveal jaundice, hepatomegaly, a poor body condition score, abdominal pain, or a fluid wave. Additional findings may include abnormalities on fundic examination (iridocyclitis or chorioretinitis) from an infectious etiology or pyrexia from infectious or inflammatory disease.

LABORATORY EVALUATION OF HEPATOBILIARY DISEASE

Clinicopathologic evaluation helps to verify the presence of liver disease and determine the degree to which other organ systems are affected. The initial database should include a complete blood count (CBC), biochemical profile, and urinalysis.

The most consistent CBC abnormalities include changes in erythrocyte size and morphology, including microcytosis, target cells, poikilocytes, and Heinz body formation (cats). Microcytosis without anemia, most likely associated with impaired iron transport, occurs in dogs and cats with congenital PSVA and in dogs with acquired shunting secondary to portal hypertension. Target cells and poikilocytes result from alteration in the erythrocyte plasma membrane lipoprotein content, causing altered cell deformability. Anemia may accompany hepatic disease either from a bleeding gastric ulcer, a coagulopathy, or the anemia of chronic disease. Some dogs with hepatobiliary disease have a mild thrombocytopenia, reflecting a systemic infectious disorder or synthetic failure from decreased hepatic thrombopoietin production.

Alanine aminotransferase (ALT), aspartate aminotransferase (AST), alkaline phosphatase (ALP), and γ -glutamyl transferase (GGT) are serum enzymes used as screening tests for hepatobiliary disease. Increases occur as a result of: (1) leakage from damaged hepatobiliary cells (ALT, AST); (2) elution from damaged membranes (ALP, GGT); or (3) increased synthesis (ALP). Although elevations in these serum enzymes have a high sensitivity for the detection of hepatobiliary damage, increases also occur in the absence of clinically important primary hepatobiliary disease. There are several reasons for this discordance. First, increases in serum hepatobiliary enzymes can originate from nonhepatic tissues. Second, in the dog endogenous or exogenous corticosteroids and phenobarbital can

induce the production of excess hepatobiliary enzymes in the absence of liver damage. Finally, the liver is uniquely susceptible to secondary injury from primary disease in other organs, particularly the pancreas and gastrointestinal tract (see Box 126-1).

Elevations in ALT and AST result secondary to leakage from damaged hepatocytes. ALT is a liver-specific cytosolic enzyme; however, increases may also occur with severe muscle necrosis in the dog. The half-life ($T_{1/2}$) of ALT is 2.5 days in dogs. No published values are available for cats; however, the $T_{1/2}$ is presumed to be much shorter (around 6 hours). The largest elevations in ALT occur with acute hepatocellular necrosis and inflammation. Mild-to-moderate elevations occur with primary hepatic neoplasia. AST, which is present in both the cytosol and mitochondria, is more sensitive but somewhat less specific for liver disease than ALT. Increases in AST typically parallel those of ALT but are of a smaller magnitude. AST elevations in excess of ALT indicate either a muscle source or the release of mitochondrial AST caused by severe irreversible hepatocellular injury. The $T_{1/2}$ of AST is 22 hours in the dog and 77 minutes in the cat.

ALP is a membrane-bound enzyme (see Chapter 127). In dogs ALP has a high sensitivity (80%) but low specificity (51%) for hepatobiliary disease. Its low specificity is caused by the presence of several isoenzymes and its sensitivity to drug induction. In the dog three isoenzymes make up the total serum ALP (T-ALP), including a bone (B-ALP), liver (L-ALP), and corticosteroid (C-ALP) isoenzyme. B-ALP comprises one third of the T-ALP in dogs and is elevated in conditions with increased osteoblastic activity such as bone growth, osteomyelitis, osteosarcoma, and secondary renal hyperparathyroidism. L-ALP is present on the luminal surface of biliary epithelial cells and the hepatocyte canalicular membrane. L-ALP $T_{1/2}$ is 70 hours in dogs and 6 hours in cats. Because of the cats' short $T_{1/2}$ and the fact that feline hepatocytes contain less ALP, increases typically do not approach those seen

in canine patients. These characteristics and the fact that cats lack C-ALP make T-ALP less sensitive (50%) but more specific (93%) for liver disease than in the dog. The largest increases in L-ALP are associated with focal or diffuse cholestatic disorders and primary hepatic neoplasms. Less dramatic increases are found in chronic hepatitis, hepatic necrosis, and canine nodular hyperplasia. C-ALP is located on the hepatocyte canalicular membrane. C-ALP increases in dogs exposed to exogenous corticosteroids or in cases of spontaneous hyperadrenocorticism; however, increases are also associated with chronic illness, possibly secondary to increases in endogenous glucocorticoid secretion.

Hepatic GGT is located on the hepatocyte canalicular membrane. In dogs GGT has a lower sensitivity (50%) but higher specificity (87%) for hepatobiliary disease than T-ALP. If an elevated ALP is noted with a concurrent increase in serum GGT, specificity for liver disease increases to 94%. The most marked elevations in GGT result from diseases of the biliary epithelium such as bile duct obstruction, cholangiohepatitis, and cholecystitis. Moderate elevations accompany primary hepatic neoplasia, whereas mild elevations result from hepatic necrosis. In cats GGT has a higher sensitivity (86%) but lower specificity (67%) for hepatobiliary disease than T-ALP. Serum GGT may be considerably greater than ALP in some cats with cirrhosis, extrahepatic bile duct obstruction (EHBD), or cholangitis. In feline idiopathic hepatic lipidosis GGT is typically only mildly elevated.

In dogs substantial increases in hepatobiliary enzymes can result secondary to corticosteroid and phenobarbital therapy. These increases may result from hepatobiliary enzyme induction and/or hepatocyte damage. Exogenous or endogenous excess of corticosteroids increases serum enzyme activity (L-ALP, C-ALP, ALT and GGT) secondary to induction. In general, the most marked increases occur in ALP and GGT, with lesser elevations in ALT. Typically induction of AST is minimal. Cessation of corticosteroid therapy in the absence of liver damage results in a gradual normalization of enzyme values over a period of 2 to 3 months. As corticosteroids induce morphologic vacuolar change in hepatocytes and have resulted in focal areas of hepatic necrosis in experimental studies, hepatocyte damage may be the cause of some of the increased enzyme activity.

Idiosyncratic hepatotoxic reactions to phenobarbital may occur in dogs, leading to chronic inflammatory disease or the hepatocutaneous syndrome. In both of these disorders moderate-to-marked increases in ALP, moderate increases in ALT, and mild increases in AST are typically seen. Phenobarbital therapy in the dog has been reported to induce the production of hepatobiliary enzymes (primarily ALP). Prospective studies to assess the relative role of induction versus damage in dogs on phenobarbital therapy have resulted in conflicting results. In one study there was no increase in ALT and ALP enzyme activity in whole-liver homogenates from phenobarbital-treated dogs, suggesting that induction was not occurring (Gaskill et al., 2005). However, another study found increased T-ALP activity in the liver of phenobarbital-treated dogs, supportive of induction (Unakami et al., 1987). Overall the available literature suggests that mild-to-moderate increases in ALP (up to five times the upper limit of normal) and ALT (usually less than two times the upper

limit of normal) may reflect enzyme induction. However, increases in GGT and AST are seldom caused by induction and may be suggestive of primary liver disease.

The magnitude of serum hepatobiliary enzyme elevation is usually proportional to the severity of active hepatobiliary damage; however, the degree of elevation is not predictive of hepatobiliary functional capacity. Marked increases in these enzymes may indicate substantial hepatobiliary injury but are not necessarily indicative of a poor prognosis because of the tremendous regenerative capacity of the liver. Alternatively normal or only mildly increased serum hepatobiliary enzymes may be seen in end-stage chronic liver disease because of replacement of hepatocytes by fibrosis and/or prolonged enzyme leakage, resulting in depletion of hepatic stores. Thus a single determination of serum hepatobiliary enzyme values has little prognostic significance. Prognostic value increases with sequential evaluation in conjunction with liver function testing and biopsy.

Assessment of liver function requires evaluation of parameters that reflect the synthetic and excretory capacity of the liver. Several hepatic function tests are included on routine biochemical testing, including bilirubin, glucose, cholesterol, blood urea nitrogen (BUN), and albumin. Although these tests are not particularly sensitive or specific, they are easily obtained and may help build a case for primary hepatobiliary disease. Hyperbilirubinemia, the most sensitive and specific of these parameters, in the face of a normal hematocrit is caused by hepatic disease resulting in inadequate uptake, conjugation and/or excretion of bilirubin, posthepatic disease interfering with biliary excretion of bilirubin, or the cholestasis of sepsis. In cholestasis of sepsis cytokines released during sepsis inhibit the expression of hepatocyte transporters necessary for bilirubin transport. Cholestasis of sepsis may occur in the presence or absence of hepatobiliary damage and appears to be common in the septic cat.

Hypoglycemia occurs only when 75% of hepatic mass is nonfunctional as a result of decreased gluconeogenesis and clearance of insulin. Hypoglycemia also occurs periodically in dogs with congenital PSVA, possibly secondary to impaired glucose production, reduced glycogen stores, decreased responsiveness to glucagon, or a combination of these factors. Serum cholesterol levels in hepatobiliary disease are variable; cholestatic disease is frequently associated with hypercholesterolemia, whereas hypocholesterolemia is seen most often in end-stage liver disease. The BUN may be low in dogs with chronic liver disease or PSVA since the hepatic conversion of ammonia to urea decreases with decreasing hepatic mass or shunting of blood past the liver. Since the liver is responsible for the synthesis of albumin, hypoalbuminemia may accompany chronic hepatic disease. Synthetic failure occurs only when 70% of hepatic functional mass has been lost. However, serum hypoalbuminemia may also occur with protein-losing nephropathies or enteropathies, vasculitis, blood loss, or from third spacing in ascitic patients.

Urinalysis in cases of hepatobiliary disease may reveal bilirubinuria or ammonium biurate crystals. Since the canine renal threshold for bilirubin is low and dogs are capable of tubular secretion of bilirubin, bilirubinuria may be present in the absence of bilirubinemia.

However, cats have a high threshold for bilirubin and are not bilirubinuric unless also bilirubinemic. Freshly collected urine samples may reveal ammonia biurate crystalluria in dogs and cats with PSVA.

Ancillary Diagnostic Tests

Hepatobiliary disease may result in ascites formation secondary to portal hypertension. Portal hypertension occurs as a result of obstruction at the level of the right atrium/cranial vena cava, hepatic parenchyma, or portal vein. Portal hypertension from the latter two causes typically results in a low-protein ascites, whereas posthepatic portal hypertension is associated with a high-protein ascites. Generally ascitic fluid caused by hepatic disease is a pure transudate but with chronicity may have characteristics of a modified transudate. An effusion bilirubin value in excess of serum bilirubin is consistent with bile duct/gallbladder rupture. Ascites is rare even in cats with end-stage liver disease.

Other ancillary clinicopathologic tests that may be indicated include serology for infectious disease (leptospirosis, ehrlichiosis, Rocky Mountain spotted fever, toxoplasmosis, neosporosis, dirofilariasis, systemic mycosis), autoantibody testing (Coombs' or antinuclear antibody) and a coagulation profile (prothrombin time [PT], partial thromboplastin time [PTT], fibrinogen levels, and fibrinogen degradation products). Coagulation test abnormalities are quite common in dogs and cats with hepatobiliary disease, although spontaneous bleeding is rare. These abnormalities may be caused by hepatic synthetic failure, vitamin K deficiency, or the presence of a consumptive coagulopathy.

In cases in which secondary hepatobiliary disease is suspected, assessment for pancreatitis (serum lipase levels/pancreatic lipase immunoreactivity) and evaluation for an underlying endocrinopathy (hypothyroidism, hyperthyroidism, hyperadrenocorticism, and adrenal hyperplasia syndromes) or gastrointestinal disease (inflammatory bowel disease) may be pursued (see Box 126-1).

Hepatobiliary Function Tests

When a minimum database suggests the presence of hepatobiliary disease, the next step generally includes specific liver function tests and abdominal imaging. In many cases a definitive diagnosis requires hepatic biopsy.

Total serum bile acids (TSBAs) are common hepatic function tests. Bile acids are synthesized from cholesterol exclusively in the liver. Once conjugated to either glycine or taurine, they are secreted into the bile and subsequently stored and concentrated within the gallbladder. After a meal cholecystokinin (CCK) release initiates gallbladder contraction; and bile acids are transported to the intestine, where they aid in the emulsification and digestion of fats. At the terminal ileum bile acids are resorbed and returned to the liver via the blood (enterohepatic circulation), where they are reextracted by hepatocytes. Normally enterohepatic circulation of bile acids occurs with 95% to 98% efficiency. Disruption of this enterohepatic circulation results in increases in TSBAs and occurs in the presence of acquired or congenital PSVA or cholestatic hepatobiliary disease. An endogenous challenge to assess

the enterohepatic circulation of bile acids is used clinically by determining TSBAs after a 12-hour fast (preprandial) and then 2 hours after a test meal (postprandial).

TSBAs have a high specificity for hepatobiliary disease. In dogs the specificity of fasting and postprandial TSBAs for hepatobiliary disease is 95% and 100% when cutoff values greater than $15\mu\text{mol/L}$ and $25\mu\text{mol/L}$ are used, respectively. In cats, using similar cutoff values, fasting and postprandial TSBAs have a specificity of 96% and 100%, respectively. The sensitivity of TSBAs for hepatobiliary disease (ranging from 54% to 74%) is not high enough to support the routine use of TSBAs as screening tests for hepatobiliary disease. The two exceptions are congenital PSVA in dogs and cats and cirrhosis in dogs in which the sensitivity of postprandial TSBAs at the above cutoff value is 100%.

A number of factors can influence the interpretation of TSBA testing. Higher fasting than postprandial values may result secondary to interdigestive gallbladder contraction or as a result of variations in gastric emptying, intestinal transit, or response to CCK release. Inaccurate postprandial values may occur because of failure of CCK release or gallbladder contraction if the test meal is inadequate in fat or amino acid content or if an insufficient amount is consumed. In addition, 2 hours may not represent the optimal time for postprandial sample collection in some animals. Finally severe ileal disease or resection can decrease the bile acid resorption, thereby decreasing postprandial TSBAs.

Interpretation of abnormal TSBAs must occur with an understanding of the test limitations. TSBAs cannot be used to discriminate one hepatobiliary disease from another or to predict the severity of the histologic lesion or degree of portosystemic shunting. When monitoring disease progression or response to therapy using sequential TSBAs, only a return to normal can be used to indicate clinical remission.

Urinary bile acids have been evaluated as a diagnostic test for hepatobiliary disease. The urinary excretion of water-soluble bile acids reflects the TSBA concentration during the period of urine formation such that persistently elevated TSBAs result in elevated urine bile acid levels. Normalized urine nonsulfated bile acids (USBAs): urine creatinine and combined normalized urine sulfated (USBAs) and USBAs: urine creatinine had a higher specificity (100% vs 67%) but lower sensitivity (62% vs 78%) than TSBAs for the diagnosis of hepatobiliary disease in dogs (Balkman et al., 2003). In the cat these urinary values were equivalent to TSBAs with respect to sensitivity (87%) and specificity (88%) for hepatobiliary disease (Trainor et al., 2003). However, in both species urine bile acids appear to have a lower sensitivity for the detection of PSVA than postprandial TSBAs.

The liver detoxifies ammonia, primarily from the gastrointestinal tract, to urea. Elevations in blood ammonia concentrations result secondary to: (1) portosystemic shunting, (2) greater than 70% reduction in liver parenchyma, and (3) inborn errors of metabolism in the urea cycle. Transient hyperammonemia has been reported in young Irish wolfhounds and with deficiencies of cobalamin and arginine in the dog and cat, respectively. Elevated fasting blood ammonia levels ($>46\mu\text{mol/L}$) have

been shown to be a sensitive (98%) and specific (89%) test for the detection of congenital or acquired PSVA in dogs (Gerritzen-Bruning, van den Ingh, and Rothuizen, 2006). Currently ammonia is the only toxin that can be measured clinically for the diagnosis of HE. The diagnostic use of blood ammonia is limited by the need for meticulous sample handling, including avoidance of hemolysis, use of cold heparinized tubes, transfer on ice, and refrigerated centrifugation and assay, all ideally within an hour of collection.

DIAGNOSTIC IMAGING IN THE EVALUATION OF HEPATOBILIARY DISEASE

The size, shape, position, opacity, and margins of the liver can be assessed on standard radiographs of the cranial abdomen. Hepatomegaly is associated with congestion (right-sided heart failure), vacuolar hepatopathy (glycogen, lipid, amyloid), infiltrative disease (neoplasia), extramedullary hematopoiesis, and inflammatory liver disease. Microhepatica may be seen with PSVA or chronic hepatitis/cirrhosis (dogs). Increased opacity may be noted secondary to mineralization within the biliary system (49% of choleliths) or hepatic parenchyma (granulomas, long-term hematomas, abscesses, neoplasia, chronic hepatopathies, or regenerative nodules). Gas may be within the biliary tree (emphysematous cholecystitis, cholangitis), portal vessels (severe necrotizing gastroenteritis), or hepatic parenchyma (hepatic abscesses).

Ultrasonography enables differentiation among focal, multifocal and diffuse disease; evaluation of the biliary system and portal vasculature; and procurement of tissue for hepatic histopathology. Focal hepatic diseases include cysts, hematomas, abscesses, granulomas, regenerative nodules, primary and metastatic neoplasms, infarcts, and biliary pseudocysts. Diffuse hyperechoic parenchyma may be noted because of fatty change (hepatic lipidosis), vacuolar hepatopathy, or cirrhosis. Diffuse hypoechoic parenchyma may be noted in cases of hepatic congestion and suppurative hepatitis. Evaluation of the biliary tree and gallbladder may reveal a gallbladder mucocele, choleliths, and intrahepatic or extrahepatic bile duct dilation. A normal ultrasound scan does not preclude a diagnosis of hepatobiliary disease.

In many cases of PSVA ultrasonography permits direct visualization of the shunting vessel. Ultrasonography is more sensitive for the detection of intrahepatic shunts (100%) than extrahepatic shunts (80% to 98%). The sensitivity of ultrasound for the diagnosis of PSVA is enhanced by duplex-Doppler or color-flow Doppler, although this requires a cooperative patient and operator patience for accurate interpretation. Reduced or reversed portal flow is seen with multiple acquired shunts secondary to portal hypertension. When combined, findings of a small liver, enlarged kidneys, and uroliths had a positive predictive value of a 100% for a congenital PSVA in dogs. Portal vein/aorta and portal vein/caudal vena cava values of greater or equal to 0.8 and 0.75, respectively, consistently ruled out an extrahepatic PSVA (d'Anjou et al., 2004).

Ultrasonography is currently the best imaging modality to evaluate for EHBDO. Ultrasonographic signs of EHBDO include dilation of the cystic duct, common bile duct

(>3 mm in dogs and >4 mm in cats), or intrahepatic bile ducts and identification of an intraluminal or extraluminal mass obstructing the biliary tract. The degree of gallbladder distention appears to be variable and thus should not be used as a sole criterion to diagnose EHBDO, particularly in cats.

Scintigraphy may be a useful adjunct in cases of suspected EHBDO or PSVA. In scintigraphic imaging of the biliary tract, an intravenous technetium 99m (^{99m}Tc)-iminodiacetic acid derivative is taken up by hepatocytes and subsequently undergoes biliary excretion. Using a cutoff of 180 minutes for the dye to enter the small intestine, the sensitivity of scintigraphy to identify complete EHBDO is high (83% to 100%), but the specificity is lower because partial bile duct obstruction may also slow dye excretion. Sensitivity remains similar, whereas specificity is markedly increased when the cutoff time is increased to 24 hours after injection. High serum bilirubin concentration did not reduce the diagnostic usefulness of scintigraphy.

Transcolonic pertechnetate scintigraphy (TCPS) is used for the detection of PSVA. In TCPS ^{99m}Tc pertechnetate is administered rectally and is subsequently absorbed into the portal venous system. In normal animals radioisotope activity is detected in the liver before its detection in the heart. In animals with PSVA the radioisotope activity is detected in the heart before the liver. In dogs TCPS has a high positive predictive value for the diagnosis of PSVA and discriminates dogs with macroscopic PSVA from those with primary hypoplasia of the portal vein since TCPS is abnormal only in the former.

Transsplenic portal scintigraphy (TSPS) can also be used to diagnose PSVA. Ultrasound-guided TSPS results in higher radioisotope count densities, more consistent splenic and portal venograms, and a significant decrease in radiation exposure when compared to TCPS. TSPS misses cases of PSVA when the shunt originates distal to the splenic vein.

The value of magnetic resonance imaging (MRI) and helical computed tomography in the diagnosis of hepatobiliary disease is currently under evaluation. MRI has shown promise in the differentiation of benign from malignant focal hepatic lesions in canine patients. Magnetic resonance angiography and helical computed tomography angiography have been used in dogs for the diagnosis of PSVA and offer the added advantage of accurate anatomic characterization of the shunt. The diagnostic use of these modalities is currently limited by both availability and cost.

HEPATIC BIOPSY ACQUISITION AND INTERPRETATION

Indications for hepatic biopsy include persistent serial increases in liver enzymes, abnormal hepatic function tests, hepatomegaly of undetermined cause, ultrasonographic abnormalities in hepatic parenchyma, and evaluation for the presence of a breed-specific hepatopathy. Hepatic biopsy can be obtained by ultrasound guidance (Tru-cut biopsy) or exploratory or laparoscopy (wedge biopsy). The advantages of the latter two methods are the ability to grossly evaluate the liver, acquire large tissue samples, and quickly identify and control postbiopsy

hemorrhage. When wedge biopsy is used as the gold standard, discordance between wedge and Tru-cut biopsies may be as high as 48% (Cole et al., 2002). However, the true gold standard for any study evaluating the accuracy of hepatic biopsies is histopathologic assessment of the whole liver at necropsy. Thus any hepatic biopsy, no matter how it is obtained, must be interpreted in light of sampling error.

Prebiopsy considerations should include the patient's overall clinical status and the risk of hemorrhage. Acquisition of hepatic tissue is contraindicated in the presence of a hemodynamically unstable patient, coagulopathy, and encephalopathy. A PT, PTT, and platelet count should be performed. Tru-cut biopsy should be avoided with elevations in PT and PTT of greater than 1.5 times normal and a platelet count of less than 80,000. A buccal mucosal bleeding time may improve the sensitivity of detecting bleeding deficiencies in cases of mild thrombocytopenia. Vitamin K is routinely administered 24 hours before hepatic biopsy. Fresh frozen plasma may be considered before biopsy in cases in which mild elevations in PT and PTT are noted.

The method of biopsy acquisition is influenced by the size of the liver, the suspected diagnosis, and the clinical condition of the patient. Microhepatica and large-volume abdominal effusion are contraindications for percutaneous ultrasound-guided biopsy. In some conditions, such as primary hypoplasia of the portal vein and nodular hyperplasia, a wedge biopsy is often necessary to obtain a definitive diagnosis. In cases of diffuse vacuolar hepatopathy, inflammatory disease, or neoplasia, a diagnosis can be obtained with a percutaneous ultrasound-guided Tru-cut biopsy (a 16-gauge needle in dogs and an 18-gauge needle in cats). Multiple biopsy samples (three to five) should be taken from different areas of the liver.

In general hepatic biopsy is preferred over fine-needle aspiration (FNA) to characterize liver disorders. When compared to hepatic biopsy, discordance rates with FNA may be as high as 70%. However, in animals with bleeding disorders or large cavitory lesions or abscesses, ultrasound-guided FNA can be performed safely. In focal or diffuse hepatic disease (vacuolar or neoplastic) FNA may yield diagnostic samples. Occasionally FNA may identify an infectious agent that can be easily missed on histopathology. However, FNA cannot reliably diagnose necroinflammatory or vascular disease. Percutaneous cholecystocentesis has been shown to be a safe technique by which to obtain bile for cytology and culture.

It is important that the clinician understand the benefits and limitations of hepatic histopathology. The purposes of obtaining hepatic tissue are to: (1) determine the category of disease (inflammatory, neoplastic, vascular, or vacuolar); (2) define the extent of the disease; (3) assess the duration of illness, and (4) provide tissue for special stains and culture to aid in the diagnosis of metabolic and infectious causes. Although histopathology may result in a definitive diagnosis in the case of metabolic disease (hepatic lipidosis) and neoplasia, more often certain reaction patterns are described, which then provide clues as to the underlying etiology. Correct interpretation of the biopsy results requires dialogue with the pathologist and reevaluation of the patient's history and clinical picture.

Since a liver biopsy specimen represents only a small portion of the entire liver and frequently even diffuse disorders have an uneven distribution, the clinician should always be critical of whether the histopathologic diagnosis fits with the clinical picture.

CHAPTER 127

Evaluation of Elevated Serum Alkaline Phosphatase in the Dog

ANTHONY T. GARY, *Little Rock, Arkansas*

DAVID C. TWEDT, *Fort Collins, Colorado*

Increased serum alkaline phosphatase (ALP) is a common laboratory finding in canine patients. In one survey of consecutive blood samples submitted to a reference laboratory, 39% of all dogs and 51% of dogs older than 8 years of age had increased ALP levels (Comazzi et al., 2004). The high sensitivity (86%) of increased ALP for detection of liver disease is complicated by the poor specificity (49%) because numerous diseases outside of the liver, as well as drugs and glucocorticoids, may induce production of the enzyme. Often the evaluation of canine patients with increased ALP becomes a diagnostic dilemma.

PATHOPHYSIOLOGY

ALP is a heterogeneous group of enzymes with poorly defined biologic functions that catalyze the hydrolysis of phosphate from various organic compounds at an alkaline pH. Normally bound to cellular membranes, ALP has been isolated from the kidney, liver, bone, placenta, and intestine. Two genes encode for ALP: tissue nonspecific (TNS) and intestinal. The products of these genes

are two isoenzyme proteins with different polypeptide sequences but similar enzymatic function. Products of the TNS gene include the isoforms of ALP that are found in the kidney, liver, bone, and placenta; and each differ only in degree of glycosylation. The intestinal gene encodes for the ALP found in the intestine (I-ALP), as well as corticosteroid ALP (C-ALP), a unique enzyme found only in the dog. Although several different isoenzymes/isoforms of ALP have been identified, only three are measured in serum because of their longer half-lives (approximately 70 hours): liver (L-ALP), bone (B-ALP), and C-ALP. The half-life of I-ALP, kidney, and placenta ALP are minutes.

Total serum ALP is the sum of L-ALP, B-ALP, and C-ALP. The proportion of each isoenzyme changes with age in normal dogs. B-ALP predominates in dogs less than 1 year of age, making up 96% of the total ALP; this proportion declines with age to approximately 25% in dogs older than 8 years of age. C-ALP comprises 10% to 30% of ALP in normal dogs, with higher proportions present in older dogs and smaller proportions in younger dogs. L-ALP is the predominant isoenzyme in dogs older than 1 year of age.

Liver Alkaline Phosphatase

L-ALP is located predominantly in the periportal zone of the liver associated with hepatocyte membranes that comprise the bile canaliculi and the sinusoidal membranes. Two mechanisms are responsible for increasing serum activity of this enzyme: cholestasis and drug induction. Induction is the increased synthesis of a protein or enzyme through modification of transcription, translation, or other processes involved in protein synthesis. Cholestasis leads to accumulation of bile salts from impaired bile flow and induces the production of L-ALP. The enzymes then accumulate on hepatocyte membranes, and solubilization of the membrane-bound enzyme occurs by the activity of glycosylphosphatidylinositol (GPI) phospholipase, an enzyme found in the plasma and on cellular membranes. Bile salts have been shown to play an important facilitatory role by increasing activity of GPI phospholipase and thus releasing L-ALP into circulation.

For L-ALP induction also occurs secondary to various drugs, most notably phenobarbital and endogenous or exogenous glucocorticoids. The underlying pathophysiologic mechanisms are poorly understood. Elevated L-ALP, B-ALP, and C-ALP were found in one study after phenobarbital administration, a finding most consistent with induction because all isoenzymes were affected (Gaskill et al., 2004). However, total L-ALP was not different between treated and untreated dogs in a separate study, an unexpected finding if induction was the primary mechanism (Gaskill et al., 2005). It is also possible that increased serum levels may be secondary to increased activity of GPI phospholipase and subsequent release of ALP in serum or by direct liver injury, causing cholestasis. Glucocorticoids have been shown to increase serum C-ALP and L-ALP through induction by increasing levels of messenger ribonucleic acid (mRNA) within 24 to 48 hours of exposure.

Corticosteroid Alkaline Phosphatase

C-ALP is a product of the I-ALP gene that only differs from I-ALP in carbohydrate composition. I-ALP is devoid of carbohydrates, whereas C-ALP is heavily glycosylated with sialic acid and is thought to be responsible for the different half-lives of the two enzymes. The hepatocyte is the site of *de novo* synthesis of C-ALP after exposure to both endogenous and exogenous glucocorticoids (Wiedmeyer et al., 2002). Expression of the I-ALP gene in the liver is delayed after exposure to steroids, as shown by increased mRNA expression and elevated L-ALP and serum C-ALP approximately 10 days after initiation of prednisone in experimental dogs. C-ALP accumulates on hepatocyte membranes in the area that comprises the bile canaliculi and sinusoidal surfaces, and elevated serum levels occur through solubilization of C-ALP by activity of GPI phospholipase.

Total ALP can be further quantified by determining the percent of C-ALP isoenzyme in the serum using electrophoresis, selective inhibition (levamisole treatment), or a heat inactivation process in the laboratory. Measuring the isoenzymes of ALP is widely available in most diagnostic laboratories but often of little clinical use. For

example, the high sensitivity (95%) of elevated C-ALP for detection of hyperadrenocorticism (HAC) is complicated by the poor specificity (18%). Elevations in C-ALP are often present with diabetes mellitus (DM), primary liver disease, or other chronic illness possibly because of stress and increases in endogenous cortisol. Although finding increased C-ALP cannot confirm the presence of HAC, it is generally accepted that low values of C-ALP decrease the likelihood of this disease. Progesterones are also thought to bind to the corticosteroid receptor on the hepatocyte and induce C-ALP production, and phenobarbital has been shown to induce production of the C-ALP isoenzyme through unknown mechanisms.

Bone Alkaline Phosphatase

B-ALP is attached to the external cellular membrane of osteoblasts. The function of the enzyme is unknown, but it likely plays a role in bone formation. Increased serum levels generally are associated with increased osteoblastic activity that occurs with bone growth in young animals, fracture healing, osteosarcoma, and less commonly nutritional osteopathies and renal secondary hyperparathyroidism. Elevations are typically mild ($<4\times$ normal) with osteosarcoma; however, they have been correlated to poor survival and are found only in tumors with increased osteoblastic activity (i.e., osteoblastic osteosarcoma). Benign familial hyperphosphatasemia has been reported in Siberian huskies and results from increases in B-ALP.

DIAGNOSTIC EVALUATION

History and Physical Examination

Evaluation of the patient with elevated ALP begins with a thorough history and physical examination (Fig. 127-1). The signalment may provide insight as to the underlying cause of ALP elevation. For instance, mild elevations in ALP ($<2\times$ normal) are often present in young growing animals because of increased B-ALP. The calcium and phosphorous are also often mildly increased in these dogs, and all three are expected findings in young dogs. Postsuckling puppies also have increases in ALP, possibly as a result of colostral ALP or induction of ALP after ingestion of colostrum. Values typically return to normal within 10 days.

Because elevated ALP may occur as a result of enzyme induction, a careful drug history should be obtained. Commonly identified drugs include glucocorticoids and phenobarbital. It is important to note that, in addition to oral steroids, topical and ocular forms may also be associated with increased ALP. Specific questioning is usually needed to ensure that other forms of steroids are not being given because topical therapy is often not considered a medication by owners and is frequently not disclosed without direct questioning. Exposure to phenobarbital or other anticonvulsants is often easily determined, but other drugs also have been associated with elevated liver enzymes and liver toxicity and are discussed elsewhere (see also Chapter 126). Various holistic herbal and nutritional supplements may also induce the production of ALP or cause liver damage. Discontinuation of the

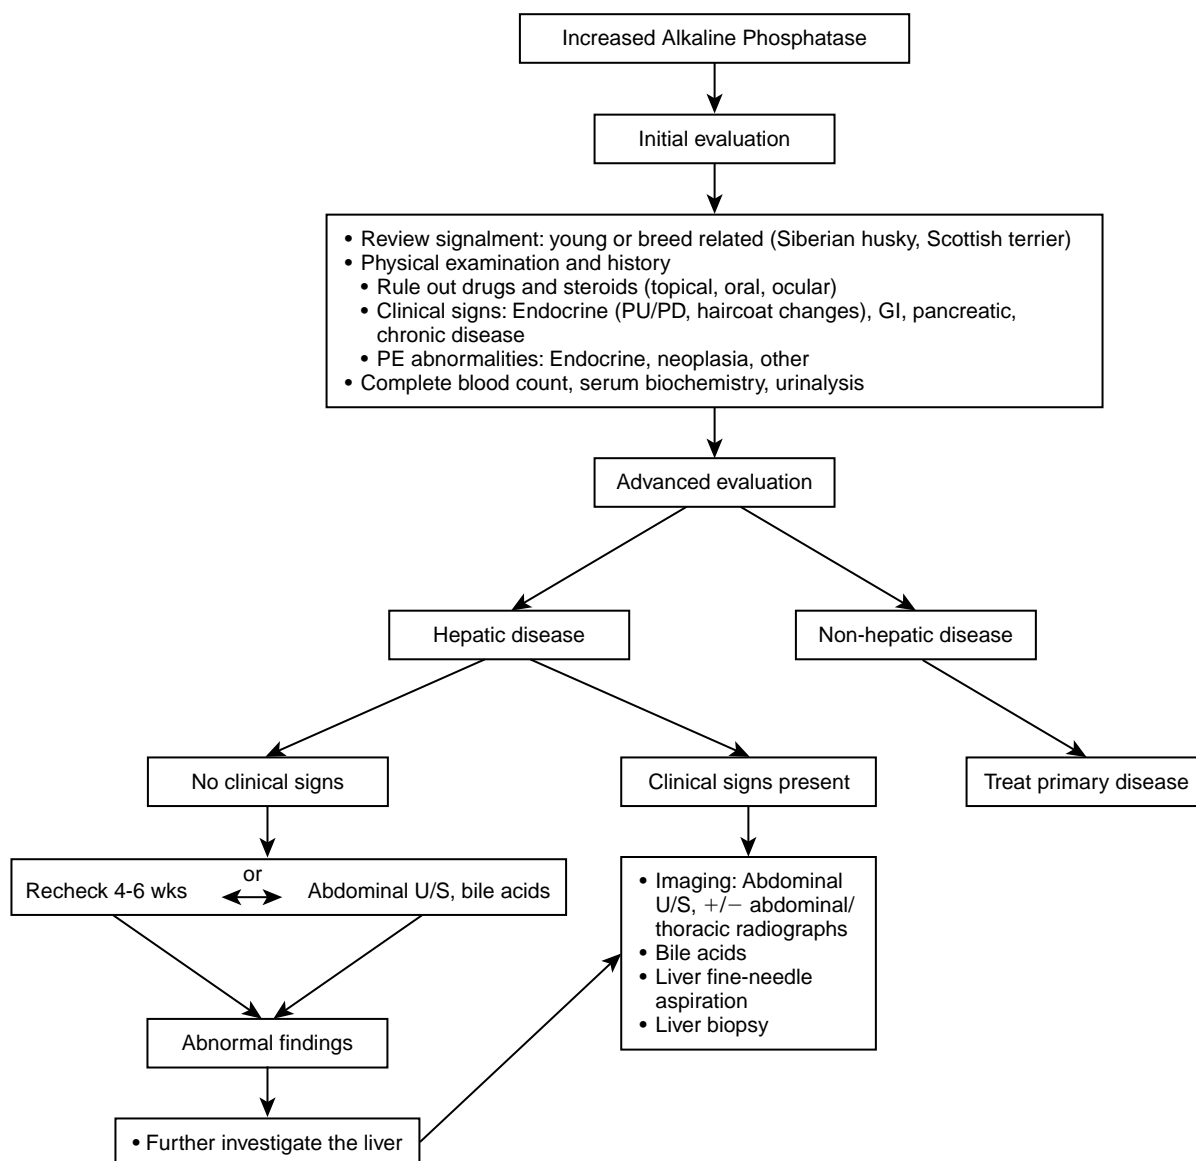

Fig. 127-1 Algorithm for evaluation of alanine phosphatase.

substance and subsequent resolution of ALP elevation over the following weeks is consistent with drug-induced abnormalities.

Endocrine diseases, including HAC, DM, and hypothyroidism, are frequently associated with elevations in ALP. The diagnosis is based on clinical findings and supportive laboratory testing. HAC is often suspected based on elevations in ALP that occur secondary to increased cortisol, as well as intrahepatic cholestasis caused by hepatocyte swelling from glycogen accumulation; this finding is present in 90% to 95% of dogs with HAC. The ALP concentrations are usually dramatically increased with HAC, whereas DM usually results in mild-to-moderate elevations in ALP (2 to 5× normal) and concurrent changes in ALT from intrahepatic cholestasis secondary to hepatocellular swelling from the metabolic derangements of the disease (hepatic lipidosis). Higher elevations in ALP may be seen from DM alone, but concurrent diseases also should be considered if this is the case (i.e.,

pancreatitis, neoplasia, primary liver disease, or HAC). Similarly ALP is occasionally increased in hypothyroid dogs, but this finding is inconsistent. Abnormal concentrations of progestins (progesterone or 17-hydroxyprogesterone) are also thought to cause increases in serum ALP in some dogs.

Preliminary Evaluation

When an elevation in serum ALP is identified, routine blood work, including complete blood count, a comprehensive serum biochemistry, and urinalysis, should be performed. Primary hepatic disease, secondary reactive hepatopathies, and induction caused by drugs are the most likely causes. Common causes are listed in Box 127-1. Nonhepatic disease is a common cause of ALP elevations, resulting from secondary reactive changes (reactive hepatopathies) occurring in the liver. Potential causes include enteritis, pancreatitis, or systemic inflammatory or infectious diseases. Histologic evidence of disease as indicated by

B-ALP, Bone alkaline phosphatase; *C-ALP*, corticosteroid alkaline phosphatase.

a variety of nonspecific reactive changes (e.g., hydropic change and periportal inflammation) is often present. Typically ALP values are threefold to fourfold above normal. Elevations in C-ALP also can result from chronic illness and endogenous glucocorticoid release. Both conditions generally cause only mild ALP elevations.

The highest values of ALP are generally seen with focal or diffuse cholestatic disease, glucocorticoid exposure, chronic hepatitis, and hepatic neoplasia. Concurrent elevations in other liver parameters (alanine aminotransferase [ALT], alanine aspartate aminotransferase [AST], γ -glutamyltransferase [GGT], and total bilirubin) are often helpful in distinguishing a cholestatic disease process from hepatocellular injury. With cholestasis, elevations in ALP, GGT, and bilirubin are expected. Elevations in the leakage enzymes ALT and AST are often present but should be of smaller magnitude when compared to cholestatic enzymes. Liver enzyme elevations primarily caused by ALT or AST are most consistent with diseases causing hepatocellular injury (i.e., chronic hepatitis).

Advanced Evaluation

Symptomatic patients. For symptomatic patients further evaluation of increased ALP is often required if elevations cannot be explained by nonhepatic diseases, drugs, or endocrine disorders. In these cases primary hepatic or biliary disease is likely, and imaging is essential to further characterize the etiology.

Although abdominal radiographs are useful for determining liver size and the presence of other abdominal abnormalities, they lack specificity with regard to hepatobiliary disease. Thoracic radiographs are obtained routinely to screen for metastatic neoplasia or other concurrent disease, especially in older patients, before more invasive diagnostics directed toward the liver.

Ultrasound is required to more fully characterize abnormalities of the biliary system and hepatic parenchyma. However, one major limitation is the variability in sonographer experience and thus the quality of the imaging procedure. Ultrasound of the hepatic parenchyma may identify masses or nodules, whereas changes in the echogenicity of the liver may suggest the presence of diffuse or focal hepatic disease. The absence of ultrasonographic abnormalities does not rule out liver disease. For example, diffuse hepatic lymphoma can be associated with hyperechoic, hypoechoic, and isoechoic hepatic parenchyma on ultrasound. In addition, dogs with benign nodular hyperplasia may have either normal or abnormal ultrasonographic changes. Lesions of the biliary system often consist of dilation of the hepatic and common bile ducts, as well as gallbladder distention, wall thickening, calculi, and sludging. Mass lesions affecting the biliary system are also commonly identified.

Specific lesions in the liver should be sampled with fine-needle aspiration (FNA) or biopsy. Often FNA is performed initially if solitary masses or diffuse hepatic changes are observed because the technique is safe and requires minimal or no sedation. In addition, FNA is often adequate to diagnose neoplasia and is used if diffuse parenchymal disease is suspected. FNA cytology results consistent with neoplasia are generally trusted, but false-positive results are possible; other findings should be interpreted with caution because FNA and histopathology may have a poor correlation based on the disease involved. Lipidosis and vacuolar hepatopathies are examples of diffuse diseases in which FNA and histology generally correlate well; however, vacuolar hepatopathy may be seen with any number of diseases, including HAC, steroid exposure, and chronic illness (Sepesy et al., 2006). Wedge or laparoscopic liver biopsy is pursued if FNA results are questionable or a histologic diagnosis is required. In addition to biopsy, collection of bile for culture, Gram staining, and cytology is recommended in dogs with evidence of biliary disease.

Preprandial and postprandial bile acids are obtained routinely to further assess liver function if diagnostic evaluation has failed to reveal the underlying cause of ALP elevation. Abnormal bile acids generally are seen with decreased liver function, acquired or congenital portosystemic shunting, and cholestasis. If results are abnormal, a liver biopsy is warranted because there is strong evidence to support

the presence of primary liver disease. However, normal bile acids do not rule out significant hepatobiliary disease; thus biopsy is also warranted in patients with or without clinical signs that have persistent or increasing ALP values that are unexplained for longer than 4 to 6 weeks.

Asymptomatic patients. Increased ALP is often found incidentally on preanesthetic or annual blood work. Initial evaluation in these patients should proceed as described previously by ruling out exposure to drugs or supplements and assessing for the possibility of nonhepatic disease, including endocrine, gastrointestinal, and neoplastic disorders. History and physical examination should be repeated to ensure that clinical abnormalities are truly absent.

Options for further evaluation include (1) monitoring ALP over time, and (2) pursuing additional diagnostics. For most cases it is appropriate to monitor ALP over 4 to 6 weeks. If progressive or persistent increases occur, further workup is indicated as described previously for symptomatic patients. Alternatively abdominal ultrasound and bile acid measurements are pursued initially to rule out obvious structural and functional abnormalities of the liver and biliary system because we have seen several cases of hepatic neoplasia in asymptomatic patients with ALP as the only clinical abnormality. The decision for additional monitoring or immediate evaluation may also be based somewhat on the degree of ALP elevation. Moderate-to-severe increases are more often associated with hepatobiliary disease or exposure to glucocorticoids and are unlikely to resolve over time.

Common hepatic causes of ALP elevation in asymptomatic patients include neoplasia, benign nodular hyperplasia, chronic hepatitis, idiopathic vacuolar hepatopathy, and breed-related conditions. Benign nodular hyperplasia, idiopathic vacuolar hepatopathy, and breed-related conditions often have ALP increases only, with little or no other liver enzyme involvement (Box 127-2). Idiopathic vacuolar hepatopathy is associated with vacuolated hepatocytes containing glycogen. In some of these cases abnormal adrenal production of progesterone or 17-hydroxyprogesterone is thought to be the cause. Adrenal steroids can be measured in conjunction with adrenocorticotrophic hormone stimulation using specific diagnostic laboratories. Some also refer to this condition as atypical Cushing's disease because liver biopsy changes are identical to those of a steroid hepatopathy. These patients often do not progress, and therapy is controversial; however, some report that melatonin or typical HAC therapy resolves hepatic changes and the elevations in C-ALP.

A common finding in Scottish terriers is ALP elevation, often without other concurrent laboratory abnormalities.

Box 127-2

Common Conditions Resulting in Only Serum ALP Elevations

- Hyperadrenocorticism
- Idiopathic vacuolar hepatopathy
- Hepatic neoplasia
- Nodular hyperplasia
- Drug induction
- Breed-related

In a recent study Scottish terriers have been shown to have a higher incidence of increased ALP (Nestor et al., 2006). An additional report describes seven Scottish terriers evaluated for increased ALP with no identifiable cause after thorough imaging, adrenocortical testing, and liver biopsy, suggesting that a benign familial hyperphosphatasemia may be present (Gallagher et al., 2006). A study that we performed found the ALP to be predominately C-ALP but failed to reveal an association between elevated endogenous steroid hormone precursors (i.e., 17-hydroxyprogesterone) and elevations in ALP in affected Scottish terriers. In fact, similar abnormalities in 17-hydroxyprogesterone and progesterone were present in terriers with high ALP and those with normal ALP. Currently the underlying cause for elevations in ALP in Scottish terriers is unknown; however, the condition appears to be benign.

Hepatic Support Therapy

BENTE FLATLAND, *Knoxville, Tennessee*

Supportive treatment of patients with hepatic disease addresses general pathophysiologic mechanisms common to many hepatic diseases. Although some treatments (e.g., antioxidants) apply to both acute and chronic disorders, supportive treatments are commonly discussed in the context of chronic inflammatory and neoplastic hepatic diseases. Some supportive treatments (e.g., antifibrotics) are by their very nature more applicable to chronic disease. Since most of these treatments are administered orally, their use in both acute and chronic cases may be limited by a patient's ability to take oral medication.

Ideally treatment of hepatic disease should be aimed at a specific underlying etiology. Given the enormous regenerative capacity of the liver, timely identification and elimination of any underlying cause offer the best hope for disease resolution in both acute and chronic cases. Evidence from human medicine suggests that fibrosis and even cirrhosis may be reversible in some cases when a specific etiology can be addressed (Rocky, 2005). In cases in which an underlying cause can be identified and eliminated, supportive care of hepatic disease may be finite. In chronic inflammatory disease, especially when the etiology is not known, or in advanced neoplastic disease when the etiology cannot be eliminated, supportive treatments are recommended indefinitely.

Our understanding of the causes of chronic inflammatory hepatobiliary disease is extremely limited, a fact that hampers research by limiting our ability to stratify patients and interpret results according to etiology. Lack of standardized supplement preparations with which to undertake clinical trials can also be a limiting factor in research. Recommendations for standardized clinical and histologic approaches to canine and feline hepatobiliary disease were recently published by the World Small Animal Veterinary Association Liver Standardization Group and, if widely adopted, should facilitate future research (Rothuizen J et al, 2006). Most recommendations for supportive care of small animal hepatic diseases, regardless of the etiology, are extrapolated from human medicine or are based on anecdotal experience and individual case reports rather than on evidence from prospective, randomized, placebo-controlled clinical trials involving large numbers of patients. The treatment recommendations in this chapter should be accepted with these limitations in mind.

Treatment of hepatic disease incorporates the following general principles:

- Address the underlying cause, if known (e.g., withdrawal of an hepatotoxic drug).
- Reduce and prevent inflammation.
- Reduce and prevent copper accumulation, if applicable.
- Reduce and prevent oxidative damage.
- Reduce and prevent fibrosis.
- Provide adequate nutrition.
- Treat complications as needed (e.g., hepatic encephalopathy, coagulopathy, gastric ulceration, fluid/electrolyte disturbances, ascites, and infection/endotoxemia)

This chapter reviews antioxidant and antifibrotic treatments commonly used for supportive care of hepatic disease and discusses treatment of hepatic disease-associated coagulopathy and ascites. For information concerning treatment of specific hepatic diseases, antiinflammatory treatments, treatment of copper accumulation, treatment of gastric ulceration, and management of hepatic encephalopathy, the reader is referred to the other chapters in this section.

ANTIOXIDANTS

It is well established that oxidative stress plays a role in the pathogenesis of liver disease in both humans and animals. Cats with hepatic lipidosis and both dogs and cats with obstructive biliary and inflammatory hepatic disorders exhibit reduced glutathione concentrations. This likely predisposes them to oxidative hepatic injury, given the ability of glutathione to detoxify reactive oxygen species. Accordingly, use of antioxidants and compounds that replenish hepatic glutathione stores seems warranted in the supportive treatment of canine and feline hepatobiliary disease (Center, Warner, and Erb, 2002). In addition to the substances discussed in the following paragraphs, zinc and ursodeoxycholate are proposed to benefit liver disease patients through antioxidant effects, although these are more often used for their copper-reducing and choleretic properties, respectively. Vitamin C (L-ascorbic acid) has also been recommended for its antioxidant and free-radical scavenging properties, but its use is less common than other antioxidants and therefore is not discussed.

Vitamin E

Vitamin E refers collectively to the antioxidant compounds known as tocopherols and tocotrienols. α -Tocopherol is the most biologically active form of vitamin E. The D stereoisomer is abundant in nature, where it is synthesized by plants. Synthetic vitamin E contains both D and L stereoisomers of α -tocopherol (Matthai, 1996). Food sources of vitamin E include vegetable oils, nuts, seeds, and grains. Because

the various vitamin E isomers have differing biologic activities, preparations of vitamin E are standardized to international units (IU). One IU is equivalent to the activity of 1 mg of synthetically prepared dl- α -tocopherol. Vitamin E is fat soluble and requires bile and pancreatic juice for maximal intestinal absorption. High dosages of vitamin E may interfere with absorption of other fat-soluble vitamins and may predispose to development of vitamin K-dependent coagulopathy. Vitamin E supplementation traditionally has been thought harmless; however, a recent metaanalysis of vitamin E use in humans with various diseases revealed that supplementation at dosages above 150 units/day was associated with increased all-cause mortality. This finding led to recommendations against vitamin E supplementation, particularly at dosages above 400 units/day (Miller et al., 2005).

In veterinary hepatology vitamin E is a commonly used antioxidant. Dosage recommendations for dogs have been reported in conference proceedings and vary from 10 units/kg every 24 hours orally to 250 or 400 units/dog every 24 hours orally. I have used the 10-unit/kg every-24-hour oral dose most commonly. Dosing small patients can be problematic since commonly available vitamin E preparations contain 400 or 1000 units. Controlled clinical trials evaluating efficacy and safety of vitamin E supplementation in canine and feline liver disease patients are unavailable. I do not recommend vitamin E supplementation in liver disease patients with evidence of vitamin K deficiency. In such cases *S*-adenosylmethionine (SAME) or milk thistle is a preferred antioxidant.

Milk Thistle (Silymarin)

The term *silymarin* refers collectively to the four flavonolignan isomers (silybin, isosilybin, silydianin, silychristine) that comprise the active ingredients of the herb milk thistle (*Silybum marianum*). Silybin is the most biologically active isomer and comprises 50% to 70% of silymarin. These flavonolignans are found throughout the milk thistle plant but are concentrated in its fruit and seeds. Commercially available preparations of silymarin vary in content and bioavailability, a fact that makes dosage recommendations difficult and hampers use of silymarin in carefully designed, prospective clinical trials. Accordingly in 2005 the National Center for Complementary and Alternative Medicine (NCCAM) issued a request for industry collaboration to develop a well-characterized, standardized formulation of silymarin that could be used in human liver disease clinical trials. If such a standardized formulation is developed, it has the potential to benefit veterinary medicine also.

The primary effect of silymarin is thought to be as an antioxidant and free-radical scavenger, but it is also proposed to have antifibrotic, antiinflammatory, and immunomodulatory actions. In humans silymarin is used primarily to treat alcoholic liver disease, viral hepatitis, and toxin-induced liver disease. Randomized controlled clinical trials using silymarin in specific human liver diseases have yet to be published.

In experimental animal models silymarin has been shown to ameliorate hepatic injury secondary to acetaminophen, carbon tetrachloride, radiation, iron over-

load, alcohol, cold ischemia, and the death cap mushroom (*Amanita phalloides*). Indeed, silymarin is so effective at reducing *A. phalloides* toxicosis by preventing hepatocyte uptake of mushroom toxins in both humans and dogs that an intravenous formulation has been developed specifically for the purpose of treating mushroom poisoning in humans (Seeff, 2001). In veterinary medicine, clinical trials evaluating efficacy of silymarin in dogs and cats with naturally occurring hepatic disease have not been published. Dosage recommendations reported in conference proceedings vary, but 20 to 50 mg/kg every 24 hours orally (dogs and cats) is commonly recommended. A veterinary product is now available containing silybin bound to phosphatidylcholine for improved gastrointestinal absorption (Marin, Nutramax Laboratories, Inc., 5 to 10 mg/kg every 24 hours orally).

S-Adenosylmethionine

SAME is present in almost all bodily tissues and fluids and is a nucleotide-like molecule synthesized from the amino acid methionine and adenosine triphosphate. Of particular importance in the liver, SAME plays a crucial role in transmethylation, transsulfuration, and aminopropylation pathways. These metabolic pathways are responsible for metabolism of various endogenous and xenobiotic compounds, generation of endogenous sulfur compounds, and production of molecules important in cell signaling and gene transcription, respectively (Center et al., 2005). Among sulfur compounds generated by the transsulfuration pathways is glutathione, an important component of the endogenous antioxidant system of the liver (Center, Warner, and Erb, 2002).

A commercial veterinary form of SAME is available (Denosyl, Nutramax Laboratories, Inc.) and has been investigated. Oral administration of SAME has been shown to significantly increase plasma SAME concentrations in dogs and cats, with a peak effect occurring 1 to 4 hours after the dose in fasted animals. SAME administration in dogs and cats increases hepatic glutathione concentrations and improves markers of red blood cell and hepatocyte redox status, justifying its use as a supportive treatment in canine and feline hepatobiliary disease (Center et al., 2005).

A recommended dosage of SAME in dogs and cats is 20 mg/kg every 24 hours orally. Administering SAME to fasted animals is recommended to maximize its absorption. Although numerous preparations of SAME are available through health food stores and other sources, these may have varying bioavailability. Use of the commercially available veterinary preparations in dogs and cats is recommended for consistency.

SAME has been shown to ameliorate oxidative stress induced by corticosteroid administration in dogs, although it does not prohibit corticosteroid-induced hepatic vacuolar change (Center et al., 2005). Clinical trials evaluating the role and efficacy of SAME in specific canine and feline liver disorders are lacking and represent the next step in our understanding of the role of SAME in the management of canine and feline hepatobiliary disease. The availability of a veterinary formulation of SAME with proven bioavailability in dogs and cats will continue to facilitate research involving this compound.

ANTIFIBROTICS

Hepatic fibrogenesis is an active area of research in human medicine, and potential therapeutic targets continue to be revealed as mechanisms of fibrogenesis are elucidated. Current understanding of hepatic fibrogenesis emphasizes the importance of hepatic stellate cells (also known as Ito cells, lipocytes, or perisinusoidal cells) in the development and maintenance of fibrosis. Future antifibrotic treatments may include compounds that interfere with hepatic stellate cell activation and/or function (Rocky, 2005).

Colchicine

Colchicine is a plant alkaloid derived from *Colchicum autumnale* (autumn crocus, meadow saffron) and has been a mainstay of antifibrotic treatment in both human and veterinary medicine. Colchicine is purported to inhibit fibrosis by binding selectively and reversibly to microtubules, inhibiting their polymerization and thus collagen secretion. Aggregate data from numerous studies of various human liver diseases reveal that colchicine generally is safe and may improve biochemical markers of, and even mortality from, hepatic disease. However, the drug does not appear to decrease fibrosis in humans, making its recommendation as an antifibrotic drug problematic. Use of colchicine has been recommended for treatment of canine hepatic diseases with fibrosis based on a few individual case reports, but critical evaluation of its efficacy in a large number of dogs has not been published. The recommended dosage for colchicine in dogs is 0.014 to 0.03 mg/kg every 24 hours orally (Honeckman, 2003). Overdosage can be fatal, as demonstrated by a case report of accidental colchicine poisoning in a dog ingesting an unknown quantity of colchicine but calculated to be between 0.5 and 3.6 mg/kg (Wagenaar, 2004). To my knowledge colchicine has not been used for treatment of feline hepatic disease, and no cat dosage is present in the veterinary literature.

Other Antifibrotics

Other substances with proposed antifibrotic effects include interferon- γ , milk thistle, penicillamine, prednisone, ursodeoxycholic acid, and zinc. None of these compounds have been critically evaluated for their ability to inhibit fibrosis in dogs and cats with liver disease, and there is no evidence to support their use specifically for that purpose at this time. Nevertheless milk thistle, penicillamine, prednisone, ursodeoxycholic acid, and zinc are already used in veterinary hepatology for other reasons (e.g., copper reduction in the case of penicillamine); thus any potential antifibrotic effect would be a coincidental benefit. For further information concerning the use of penicillamine, ursodeoxycholate, and zinc, the reader is referred to Chapters 129 and 130 in this section.

TREATMENT OF HEPATIC DISEASE-ASSOCIATED COAGULOPATHY

Although coagulopathy is a common complication of hepatic disease, spontaneous bleeding in hepatic disease patients is uncommon. Bleeding is usually induced by a hemostatic

challenge such as venipuncture, surgical procedures, or gastric ulceration. In hepatic disease mechanisms of coagulopathy include decreased synthesis of vitamin K-dependent coagulation factors (factors II, VII, IX, and X) and development of disseminated intravascular coagulation (DIC). Patients in which DIC is identified should be treated as needed with fresh frozen plasma and heparin.

Mechanisms of reduced vitamin K-dependent coagulation factor synthesis in hepatic disease include lack of dietary vitamin K intake, poor vitamin K absorption caused by cholestasis, altered bacterial flora associated with antibiotic usage, and/or hepatic dysfunction-associated impairment of the vitamin K epoxide cycle. Vitamin K-dependent coagulation abnormalities may be identified and should be monitored using prothrombin time (PT) or proteins induced by vitamin K absence or antagonism (PIVKA). Evaluation of clotting times should be performed routinely before hepatic biopsy. Parenteral vitamin K₁ (phytonadione) at a dosage of 0.5 to 2 mg/kg every 12 hours subcutaneously for two to three dosages (or until normalization of PT or PIVKA concentrations) is recommended for dogs and cats with hepatic disease (smaller patients should receive the lower end of this dosage range) (Honeckman, 2003). In affected patients vitamin K supplementation is recommended for 24 to 36 hours before invasive procedures such as hepatic biopsy or feeding tube placement.

TREATMENT OF HEPATIC DISEASE-ASSOCIATED ASCITES

Ascites caused by hepatic disease is most often caused by a combination of portal hypertension and low colloid osmotic pressure resulting from hypoalbuminemia. Patients having complete portal vein obstruction (e.g., from thrombosis) develop very high portal pressure and may develop ascites from this mechanism alone. Cats rarely develop ascites secondary to hepatic disease. Accumulation of ascites and the associated relative or absolute reductions in circulating blood volume activate the rennin-angiotensin-aldosterone system, causing sodium and water retention and potassium loss.

Apart from resolving the underlying mechanism, the mainstay of supportive care for ascites is the cautious use of diuretics. The goal of diuretic therapy is not complete elimination of ascites but rather to keep the patient comfortable. Furosemide, a loop diuretic, causes renal potassium loss; and high dosages of this drug should be avoided in liver disease patients. Spironolactone, an aldosterone receptor antagonist, spares potassium loss and is the preferred diuretic, although it is relatively weak in terms of diuretic effect. The dosage of spironolactone is 1 to 4 mg/kg every 12 hours orally (dogs) or 1 to 2 mg/kg every 12 to 24 hours orally (cats). Starting at the low end of the dosage range is recommended, and the dose may be titrated upward at weekly intervals if no affect is achieved. If the recommended dosage of spironolactone does not control ascites adequately, it may be used in combination with furosemide 1 to 2 mg/kg every 12 to 24 hours orally. Potential side effects of spironolactone and furosemide are dehydration and electrolyte imbalances. Skin lesions have been reported in cats receiving spironolactone chronically.

Other considerations when treating hepatic disease patients with ascites include addressing the underlying cause of hepatic disease if possible, feeding a sodium-restricted diet, and maintaining adequate hydration and a normal serum potassium concentration. Abdominocentesis should be considered only for diagnostic purposes and to relieve tense ascites that is causing discomfort and/or impaired respiration. Removing large volumes of ascitic fluid is discouraged since this may promote dehydration and exacerbate hypoproteinemia.

CHAPTER 129

Copper-Associated Chronic Hepatitis

GABY HOFFMANN, *Utrecht, The Netherlands*
JAN ROTHUIZEN, *Utrecht, The Netherlands*

Hepatic copper accumulation can result from increased uptake of copper, a primary defect in hepatic copper metabolism, or altered biliary excretion of copper. Copper toxicity depends on the molecular association and subcellular localization of the molecule, as well as the total concentration of copper in liver tissue. In inherited copper storage disorders copper accumulation is always localized centrolobularly (e.g., Bedlington terrier copper toxicosis, Wilson's disease in humans, liver disease in Long-Evans Cinnamon rats). In secondary copper loading of liver cells during cholestasis, copper is mainly restricted to the periportal parenchyma.

COPPER METABOLISM

Forty to 60% of the ingested copper is absorbed from the upper small intestine. Copper transporter 1 (CTR1) is responsible for hepatocellular uptake of copper. In the liver cell copper is immediately bound to the transport proteins COX17, ATOX1 and CCS, which deliver cop-

per to their target destination in the cell. These targets include superoxide dismutase, which depends on copper for appropriate function, and mitochondrial enzymes of the respiratory chain. In the Golgi apparatus the ATPases ATP7A (Menkes disease protein) and ATP7B (Wilson's disease protein) are responsible for preparation of copper excretion. For excretion into the bloodstream copper is bound to ceruloplasmin. In conditions of copper excess excretion of the metal into bile occurs via interaction with copper metabolism murr1 domain-containing protein 1 (COMMD1). Metallothionein is responsible for copper storage. A summary of the proteins involved in copper metabolism is given in Fig. 129-1.

INHERITED COPPER-ASSOCIATED CHRONIC HEPATITIS

Inherited copper toxicosis is a well-described disease in the Bedlington terrier, in which a deletion of exon 2 in the COMMD1 gene (previously called *MURR1*) causes

Fig. 129-1 Hepatic copper metabolism. Normal hepatic copper metabolism involves several intracellular pathways. Free copper has a high potential for oxidative damage; therefore there is basically no free copper present in the cell. Copper is excreted into blood after incorporation in ceruloplasmin. Excessive copper is excreted into bile. *CTR1*, copper transporter 1; *COX17*, *CCS*, *ATOX1*, target specific copper transporters; *ATP7A*, Menkes disease protein; *ATP7B*, Wilson's disease protein; *SOD*, superoxide-dismutase1; *COX*, cytochrome-c-oxidase; *MURR1*=*COMMD1*, copper metabolism murr1 domain-containing protein 1.

accumulation of copper in hepatocytes, resulting in chronic hepatitis. Hepatic copper storage and associated hepatitis are also breed associated in the West Highland white terrier, Skye terrier, Doberman, dalmatian, and Labrador retriever (Haywood, Rutgers, and Christian, 2006; Hoffmann et al., 2006; Mandigers et al., 2004; Thornburg et al., 1986; Webb, Twedt, and Meyer, 2002).

The average canine liver copper concentration is 200 to 400 ppm (ppm = mcg/g = mg/kg) per dry weight (DW) liver. Hepatic copper levels in breeds with primary copper storage disease vary among individual animals and among breeds from 600 to above 2200 ppm. Normal copper concentrations appear to vary little from breed to breed (Table 129-1).

Clinical Findings

Dogs with inherited copper-associated hepatitis may begin to accumulate copper at 5 to 6 months of age but may appear normal for years before they develop clinical signs late in the disease process. One investigator followed Bedlington terriers with the COMMD1 deletion from birth to 3 years of age. Copper accumulated in the liver by 1 year of age, but histologic signs of hepatitis did not occur before affected dogs were 2 years old. It appears

that dogs with inherited copper storage disorders may be subject to a prolonged initial delay period of several years between severe accumulation of copper and development of histologic evidence of inflammation and a second delay between histologic evidence of inflammation and recognition of clinical symptoms of disease.

With the exception of hemolysis from hepatic copper release into blood, which is only described for Bedlington terriers, symptoms of the disease are generally nonspecific and result from liver dysfunction. The clinical signs may start with a calmer behavior or loss of appetite. In most cases the owner only recognizes these intermittent signs retrospectively. Over weeks to months dogs may have days of decreased activity and long periods when they appear completely normal. After months to years the symptoms become more evident. The affected dogs may salivate and have intermittent vomiting and nausea. Polyuria and polydipsia, icterus, diarrhea, and ascites may develop in advanced disease (Box 129-1).

A clue to the diagnosis would be elevations in liver-specific enzymes or evidence of loss of liver function. Because copper-associated liver disease is a hepatocellular disorder, alanine aminotransferase (ALT) activity is relatively greater when compared to alkaline phosphatase

Table 129-1

Normal Range for Hepatic Copper in Liver Tissue of Dogs

Range (ppm per dw)	Normal Range	Breed	Method	Dogs
91-358	206 ± 56	Bedlington terriers	sp	22
94-270	190 ± 56	Mixed breed dogs	sp	15
60-270	155 ± 66	Mixed breed dogs	sp	13
38-650	156 ± 119	5 mixed breed dogs + 32 pure breeds	sp	37
100-700	197 ± 113	Doberman Pinscher	NAA	13
120-304	<400	Labrador retrievers	NAA	6

DW, Dry weight; NAA, neutron activation analysis; sp, spectroscopy.
Note that ppm equals mcg/g and mg/kg per dry weight.

- Icterus
- Ascites
- Seizures

activity. ALT elevation is the first and most consistent laboratory abnormality reported in Bedlington terriers with inherited copper toxicosis. Radiologic examination does not usually provide specific findings characteristic for chronic hepatitis. Ultrasound examination is helpful to exclude other diseases. Liver size is normal in most cases but may be decreased in cirrhosis. Echogenicity can be normal, increased, decreased, or irregular with a patchy appearance.

Diagnostic Criteria**Histology**

Histopathologic evaluation of liver tissue is the only method for a definitive clinical diagnosis of the disease. Two or more liver biopsies, taken with a large-core needle (suggested 14 gauge), are a required minimum to evaluate liver tissue and to determine hepatic copper concentrations quantitatively or semiquantitatively.

The typical magnitude and localization of copper within zone 3 in the liver lobule is characteristic of primary copper storage diseases. As copper accumulates in hepatocytes, hepatocellular inflammation with copper-laden macrophages and chronic hepatitis result. Histology of chronic hepatitis is characterized by hepatocellular apoptosis, necrosis, regeneration, and fibrosis, as well as inflammatory infiltrates, which can be mononuclear or mixed. Cirrhosis results as the end stage of the disease. Fibrosis is part of the pathologic definition of chronic hepatitis but may appear very late in the disease process. Therefore early in the disease histology may not immediately reflect characteristic changes in chronic hepatitis and requires follow-up examinations.

Copper Assessment

Copper concentrations in liver tissue can be assessed quantitatively by irradiation of biopsies and measurement of the induced copper radioactivity in small amounts of tissue (2mg of tissue) or by spectrophotometric methods on larger pieces of fresh frozen liver (1 to 2g of tissue needed). For the latter method formalin-fixed tissue can be submitted, but measurement of copper concentrations in wet weight liver tissue is not recommended because the reference range for copper is established on a DW basis.

Box 129-2

A Histochemical Grading System for Assessment of Canine Liver Tissue Stained With Rhodanine or Rubeanic Acid*

0. No copper
1. Solitary liver cells with some copper-positive granules
2. Small groups of liver cells with small-to-moderate amounts of copper-positive granules
3. Larger groups or areas of liver cells with moderate amounts of copper-positive granules
4. Large areas of liver cells and RHS cells with many copper-positive granules
5. Diffuse presence of liver cells and RHS cells with many copper-positive granules

*Copper scores above 2 are abnormal (see Fig. 129-2 for photographs) RHS, Reticulohistiocytosis.

Alternatively histochemical stains, using rubeanic acid and rhodanine, can be used to assess liver tissue copper accumulation semiquantitatively. These stains consistently detect copper in liver specimens when amounts exceed the normal range of 400mcg/g DW.

A histochemical grading system for evaluation of liver tissue stained with rhodanine was developed by Johnson (1984) for semiquantitative evaluation of hepatic copper concentrations in Bedlington terriers. The same grading system was applied for assessment of semiquantitative copper scores in rubeanic acid-stained liver tissue of Bedlington terriers, Doberman pinchers, and Labrador retrievers. A grading scale of 0 to 5 is used, with 0 having no copper. According to both staining methods copper scores above 2 are considered abnormal (Box 129-2). Fig. 129-2 shows histochemically stained samples in dogs with copper accumulation.

Specific Breeds**Bedlington Terrier**

Hepatic copper toxicity was first identified in Bedlington terriers in 1975. It was subsequently shown that affected dogs have an inherited autosomal-recessive defect of the MURR1 gene, which was renamed to COMMD1. The extent of hepatic damage tends to parallel the increasing hepatic copper concentrations, which result from decreased copper excretion into bile in COMMD1-deficient liver cells. The accumulated copper in liver tissue is seen as dense granules in lysosomes and occurs mainly in the centrolobular region of the liver lobule. The histologic changes extend from focal necrosis to chronic hepatitis and cirrhosis. In some cases acute hepatic necrosis, copper-associated hemolytic anemia, and acute liver failure may occur. Female and male dogs are affected equally.

Copper toxicosis in Bedlington terriers can be divided into three stages clinically. In the first stage hepatic copper concentrations increase from 400 to 1500ppm DW. Copper accumulation occurs in the centrolobular hepatocytes (zone 3). This stage remains clinically silent. A liver biopsy reveals increased concentrations of copper. The

Fig. 129-2 Histology slides (3-µm thickness) of liver tissue from dogs stained with rubeanic acid stain for copper showing different histochemical grades. *P*, portal area; A, score 2+; B, score 3+; C, score 4+; D, score 5+ according to Box 129-2. (Courtesy Dr. T.S.G.A.M van den Ingh, TCCI Consultancy BV, Utrecht, The Netherlands.)

histologic liver structure is normal but stains positive for copper granules.

In the second stage copper concentrations increase further in a range of 1500 to 2000 ppm DW. Histologically copper accumulation is now also found in the midzonal and periportal hepatocytes (zones 2 and 1). A liver biopsy reveals inflammation. Mixed cell foci can be found centrilobular and contain necrotic hepatocytes, lymphocytes, plasma cells, neutrophils, and copper-laden macrophages. In the most advanced stage the dogs become clinically ill. Copper concentrations usually exceed 2000 ppm DW. Histology reveals hepatitis and cirrhosis. Cholestasis and bile duct proliferation occur along with fibrosis possibly because of the compression exerted on bile ducts in a distorted fibrotic liver and a cytokine-induced proliferation of bile ducts.

Heterozygous carrier dogs show increases of hepatic copper concentrations out of the normal range until around 6 to 9 months of age before concentrations fall back into the normal range. Liver biopsies in dogs under 1 year of age do not differentiate carrier dogs from those in affected dogs.

Affected dogs are diagnosed by either copper measurement in liver biopsies and/or genetic testing. Estimates of the incidence of copper toxicosis in Bedlington terriers varied between 34% and 66% before genetic testing became available. Genetic assays are commercially available that determine the presence of a particular microsatellite marker, which is in linkage disequilibrium with the COMMD1 mutation, or they detect the deletion of exon 2 of COMMD1 directly.

Doberman Pinscher

The disease almost exclusively affects female Dobermans, beginning in young dogs (1 to 3 years of age) with increased ALT concentrations, centrilobular copper accumulation, and subclinical hepatitis. Clinical evidence of liver disease usually begins around 4 to 7 years of age with chronic hepatitis and cirrhosis. Copper appears to be associated with the disease because recent studies found that copper was often increased before development of clinical hepatitis (Mandigers et al., 2004). Copper excretion studies also found decreased biliary excretion of copper in affected dogs. Copper chelator therapy with penicillamine

in subclinical dogs normalized copper concentrations, with improvement in the grade of histologic damage.

Dalmatian

A retrospective study summarized 10 dalmatians with copper-associated chronic hepatitis (Webb, Twedt, and Meyer, 2002). Two of the dogs were related, and all presented for gastrointestinal clinical signs. Males and females were affected equally, and all dogs had elevated liver enzymes and necroinflammatory liver changes, as well as centrolobular copper accumulations. In five dogs hepatic copper concentrations exceeded 2000 mcg/g DW liver.

West Highland White Terrier

The described dogs ranged from 3 to 7 years of age. Some dogs had elevated hepatic copper concentrations (centrolobular) but no evidence of liver disease, which led to the suspicion that copper may later develop into chronic hepatitis or cirrhosis. Copper accumulation does not appear to increase with age in the West Highland white terrier, and there is no gender preference (Thornburg et al., 1986). Biliary excretion studies revealed a decreased excretion of radioactive copper in affected dogs.

Skye Terriers

Cholestasis was suspected as the etiology of copper-associated chronic hepatitis/cirrhosis in Skye terriers. The 10 described dogs were 1 to 10 years old. Female and male dogs were affected equally and presented with intermittent anorexia, vomiting, and ascites. At a terminal stage of the disease the animals developed jaundice and died (Haywood, Rutgers, and Christian, 1988). Further studies are required to better describe this syndrome in Skye terriers.

Labrador Retriever

Chronic hepatitis is reported to be common in this breed, and copper accumulation is associated with about 75% of the cases. Females are more commonly affected and generally present around 7 years of age (range 2 to 10 years). Clinical symptoms are nonspecific, including anorexia, vomiting, and weight loss. Hepatic copper concentrations generally range between 650 and 3000 mcg/g DW liver and a histochemical grade greater than 2+ using rubeanic acid staining. The histologic localization of copper in the centrolobular region of the liver lobule suggests primary copper accumulation (Hoffmann et al., 2006).

Other Breeds

An Anatolian shepherd, 6 German Shepherds, 11 keeshonds, a boxer, and 2 cats have been reported to have liver disease associated with hepatic copper accumulation.

Copper Accumulation Secondary to Cholestasis

Copper may accumulate in the liver secondary to cholestatic liver diseases. This is a result of defective copper excretion via bile. Cholestatic liver diseases often result in copper accumulation in the periportal areas. The magnitude of copper accumulation from cholestasis is not as

high as in inherited copper storage disorders. In a review of 17 liver biopsies from breeds not yet identified to have inherited copper-associated liver disease, the mean copper concentration was 984 mcg/g DW liver. Another study found that a 3+ or higher histochemical grade for detection of copper in the central area of the liver lobule indicates a primary copper storage disease (Spee et al., 2006). In this study the authors were able to find clear distinction criteria to determine whether copper accumulation is primary or secondary to hepatitis by comparing liver biopsies from Bedlington terriers with copper toxicosis with noncopper-associated breeds and chronic extrahepatic cholestasis. Copper metabolism and oxidative stress were analyzed using histochemical staining and quantitative reverse transcriptase polymerase chain reaction to compare the expression of genes that are involved in copper metabolism and protection against oxidative stress. This approach allowed the authors to identify expression profiles of certain genes that are characteristic for primary hepatic copper storage disorders.

TREATMENT

Chelator Therapy

Penicillamine

Penicillamine chelates a variety of metals, including copper. The drug leads to mobilization of copper from tissues and promotes copper excretion in urine. Penicillamine may also increase the synthesis of metallothionein (a copper-binding protein) and has antiinflammatory, immunosuppressive, and antifibrotic effects. Because of potential teratogenic effects of penicillamine, owners should be informed about safe handling of the drug (gloves for breaking pills or opening capsules), and pregnant women should not come in contact with the drug. The recommended dosage of penicillamine for dogs is 10 to 15 mg/kg every 12 hours orally. Lifelong therapy may be required. Adverse effects such as anorexia, vomiting, and diarrhea occur frequently in dogs. Most of these adverse effects can be avoided by mixing the drug with food and dividing the dose to more frequent dosing intervals per day. Adverse effects from long-term therapy with penicillamine may include anemia (normocytic or microcytic) and glycogen storage of the liver. Patients should be monitored clinically, as well as by 6-month assessments of the complete blood count and an annual-to-biennial liver biopsy. Side effects reported in humans include vitamin B deficiency from increased urinary loss and lupus-like symptoms with lymphadenopathy, cytopenias, fever, cutaneous eruptions, and proteinuria. Penicillamine is teratogenic and may cross the placenta; thus use during pregnancy is not recommended.

Clinical improvement from penicillamine treatment takes weeks to months, and there are large interindividual variations with respect to the effectiveness of the drug. Therefore follow-up liver biopsies are required to determine the effectiveness of chelation. One author describes an average detoxification rate of around 900-ppm copper decrease per year during penicillamine treatment in Bedlington terriers (Rolfe and Twedt, 1995).

Penicillamine was effective for treatment of Doberman pinschers with copper-associated subclinical hepatitis.

We have also tested copper chelation therapy with penicillamine in Labrador retrievers in a randomized, double-blinded, placebo-controlled study and found the drug to be effective given 10 to 15 mg/kg every 12 hours orally for 3 to 6 months.

Trientine

Trientine hydrochloride (Syprine) is available in the United States for humans intolerant to penicillamine. Although clinical experience with the drug is limited, from current knowledge trientine may have fewer gastrointestinal effects than penicillamine in dogs. Trientine is a copper chelator that acts by increasing urinary excretion of copper. In addition, the drug may also help to decrease intestinal absorption of copper. One investigator described trientine as more potent than penicillamine for decreasing copper concentrations in plasma and concluded that the drug might be superior for treatment of acute hemolytic crisis (Twedt, Hunsaker, and Allen, 1988). Trientine has teratogenic effects in animals. Therefore owners need to be informed about safe handling. The recommended dosage is 10 to 15 mg/kg every 12 hours orally 1 to 2 hours before feeding.

Zinc

Oral zinc is given to reduce copper absorption from the diet. Recommended dosage is 100mg of elemental zinc every 12 hours orally per dog. Zinc given orally induces the production of metallothionein in intestinal mucosal cells. Metallothionein binds copper from the diet and therefore prevents the uptake of copper into the circulation. Since the rate of removal of hepatic copper is relatively slow, dogs with severe or fulminant copper-induced hepatitis should not be treated with zinc therapy alone. Theoretically zinc given orally together with penicillamine may decrease the effectiveness of both drugs.

The type of zinc salt used does not influence efficacy of the drug but may affect tolerability. Gluconate may be more tolerable than sulfate and acetate. Theoretically zinc should be given apart from feeding because some food constituents (such as phytates) can bind zinc and diminish efficacy. Zinc is often a gastric mucosa irritant, leading to nausea and vomiting. Mixing the drug with small amounts of food has been recommended. Plasma zinc concentrations of normal dogs range between 90 and 120mcg/dl. Plasma zinc concentrations above 200mcg/dl are required during therapy to suppress copper uptake, but at plasma zinc concentrations above 1000mcg/dl hemolysis may occur. Serum zinc concentrations should be monitored monthly for several months to ensure that concentrations are in the therapeutic range. In a study of three Bedlington terriers and three West Highland white terriers with copper toxicosis,

200mg of elemental zinc was given daily to each dog to achieve therapeutic plasma concentrations of zinc above 200mcg/dl. Effectiveness of zinc for prevention of copper uptake from the intestine was assessed by measurement of peak plasma concentrations of radioactive copper. A minimum of 3 months of zinc treatment was necessary before copper uptake from the intestine was blocked. Although zinc is currently reserved for maintenance treatment, it has been used as first-line therapy in asymptomatic humans.

Dietary Management

The goal of dietary medical therapy is to reduce the absorption of copper from the intestinal tract. Heavily copper-supplemented diets or copper-containing vitamin-mineral supplements should be avoided. Foods with excessive copper such as eggs, liver, shellfish, organ meats, beans, mushrooms, chocolate, nuts, and cereals should be excluded from the diet (Rolfe and Twedt, 1995).

Balanced low-copper diets are commercially available for dogs. Although the effectiveness of such diets to prevent further copper accumulation has not been tested in controlled studies, dietary management seems a reasonable choice as an auxiliary measure during treatment for copper-associated liver diseases.

Ursodeoxycholic Acid Therapy

CYNTHIA R.L. WEBSTER, *Grafton, Massachusetts*

For many years practitioners of Eastern medicine have known of the healing powers of Chinese black bear bile. The major bile acid in this bear's bile, ursodeoxycholic acid (UDCA), has been commercially synthesized and marketed as a hepatoprotective agent in Japan since the 1930s. It was not until the 1970s that Western medicine began to appreciate the medicinal value of UDCA when a synthetic version of this bile acid received approval (Actigall, Watson) to be marketed for the dissolution of cholesterol gallstones in humans. In the 1980s physicians noticed that UDCA therapy in patients with concurrent gallstones and chronic hepatic disease resulted in improvement in liver function test results. Since then numerous studies have demonstrated the beneficial action of UDCA in treating a variety of hepatopathies. In 1998 a second form of UDCA (URSO, Axcan Pharma) was approved to treat primary biliary cirrhosis (PBC), an autoimmune disease of the intrahepatic bile ducts in humans.

HEPATOPROTECTIVE ACTIONS OF URSODEOXYCHOLIC ACID

Mammalian bile acids are actually a family of amphipathic organic anions that share a steroid nucleus with hydroxylation at the 3 position. The primary bile acids synthesized from cholesterol in the liver, chenodeoxycholic acid and cholic acid, are characterized by additional hydroxylations at the 7 and the 7 and 12 positions, respectively. These primary bile acids are conjugated in the liver with either glycine or taurine. In humans the major circulating bile acid is the di-hydroxy bile acid glycochenodeoxycholate, whereas in the dog and cat it is the tri-hydroxy bile acid taurocholate. Bile acid conjugation and hydroxylation increase the aqueous solubility of bile acids and by doing so decrease their passive resorption in the biliary tract and intestine. This permits the accumulation of the high biliary and intestinal bile acid concentrations necessary for their role in maintaining bile flow and fat absorption. Although the exact mechanism(s) responsible for this hepatoprotective effect of UDCA have not been fully characterized, the following beneficial actions have been proposed: (1) replacement of the more hydrophobic hepatotoxic bile acids in the circulating pool, (2) induction of choleresis, (3) stabilization of mitochondrial function, and (4) immunomodulation.

Some members of the bile acid family are hepatotoxic and, depending on their concentration, lead to apoptosis (at 50 to 200 μ M) or necrosis (at >500 μ M). Since many hepatobiliary diseases are accompanied by increases in serum and hepatic concentration of bile acids of this mag-

nitude, it is likely that bile acids contribute to the pathologic progression of these disorders. The relative toxicity of bile acids is loosely correlated with their degree of hydrophobicity. Both bile acid conjugation and hydroxylation decrease hydrophobicity and thus toxicity. UDCA, a di-hydroxy bile acid, is a relatively hydrophilic, non-hepatotoxic bile acid even though it is almost structurally identical to the much more hepatotoxic bile acid, chenodeoxycholate. This discrepancy is in part explained by the orientation of the hydroxyl groups in the two molecules. In chenodeoxycholate the OH groups are oriented at the α -face of the steroid nucleus, leaving a large hydrophobic face. In UDCA the 7-OH group is oriented at the β -face of the steroid nucleus, rendering the molecule much more hydrophilic. Thus one mechanism by which UDCA may be hepatoprotective is by replacing more hydrophobic hepatotoxic bile acids such as chenodeoxycholate from the circulating bile acid pool. However, this view is overly simplistic, since in humans a correlation between enrichment of the bile acid pool with UDCA and its therapeutic effect has been hard to demonstrate. In addition, this effect would be of limited value in dogs and cats in which the major circulating bile acid is the relatively nontoxic tri-OH bile acid cholate.

UDCA is a potent choleretic agent. Induction of choleresis stimulates the biliary excretion of bile acids and other potentially toxic endogenous metabolites that are retained during cholestasis such as copper, leukotrienes, bilirubin, and cholesterol. UDCA-induced choleresis occurs by two mechanisms. The most important means is by increasing the plasma membrane expression of membrane transporter necessary to generate bile flow. This is accomplished by mobilizing intracellular stores of the transporters through activation of signal transduction molecules such as protein kinase C. A second mechanism whereby UDCA promotes choleresis is known as cholehepatic shunting. Unconjugated UDCA is secreted into bile, where it becomes protonated, leading to the generation of bicarbonate ion. Protonated UDCA is then passively absorbed by the biliary epithelial cells, leaving the net secretion of one bicarbonate ion. The bicarbonate then serves as an osmotic draw for biliary water secretion.

In hepatocytes UDCA prevents apoptosis caused by several important physiologic stimuli, including ethanol, Fas ligand, tumor necrosis factor (TNF), and bile acids. In addition, UDCA protects nonhepatic cells, most notably colonic epithelial cells, neurons, and cardiac myocytes, from apoptosis. Accumulating evidence suggests that UDCA mediates its antiapoptotic effect by stabilizing mitochondrial function. Mitochondria are key regulators of apoptotic pathways. When cells receive a death signal,

whether from a death receptor (Fas, TNF) or from intracellular stress, small proteins of the Bcl-2 family such as Bax and Bid translocate from the cytosol to the mitochondria. Together these proteins integrate into the mitochondrial membrane, disrupt membrane permeability, and lead to the release of apoptogenic factors that ultimately lead to cell death. UDCA protects mitochondria by decreasing the cellular expression of Bax and preventing Bax translocation to the mitochondria. UDCA can also directly interact with mitochondrial membranes to inhibit Bax-mediated membrane perturbations. As a result of its protective effects on mitochondria, UDCA prevents the loss of mitochondrial membrane potential during apoptosis and decreases the mitochondrial production of reactive oxygen species. UDCA also increases mitochondrial glutathione levels perhaps by stabilizing mitochondrial membrane transporters or by increasing the activity of methionine adenosyltransferase. The latter effect would lead to increased generation of *S*-adenosylmethionine, which can then be metabolized by transsulfuration to glutathione. Glutathione is the major antioxidant in the liver and an especially important free-radical scavenger in the mitochondria. The cellular basis for the antiapoptotic actions of UDCA on the mitochondria likely involves stimulation of cellular survival signaling. In hepatocytes, neurons, and cardiac myocytes, UDCA protection against cell death requires activation of the lipid kinase phosphoinositide-3-kinase and downstream activation of the serine/threonine kinase AKT. UDCA-mediated activation of mitogen-activated kinases has also been implicated in its protective effect in hepatocytes.

Several immunomodulating effects of UDCA have been reported. UDCA decreases the production of immunoglobulin by B lymphocytes and interleukin-1 and interleukin-2 by T lymphocytes in response to nonspecific stimuli. UDCA treatment also decreases expression of hepatocyte cell surface membrane HLA class I molecules. Several studies suggest that UDCA works as a biologic response modifier of the glucocorticoid receptor (GR). Glucocorticoids bind to cytosolic GRs, resulting in translocation of the receptor to the nucleus. In the nucleus the GR interacts with the glucocorticoid response element to modulate the transcription of genes involved in inflammation. The cortisol-GR complex also regulates the action of another proinflammatory transcription factor, nuclear factor- κ - β (NF- κ - β). Studies show that UDCA activates the GR by binding to a region distinct from that to which glucocorticoids bind. The UDCA-GR complex translocates to the nucleus and can block NF- κ - β -mediated transcription. The importance of GR binding in the cytoprotective effect of UDCA has been demonstrated in hepatocytes where small interfering RNAs that prevent the UDCA-GR interaction abolish the protective effect of UDCA in cytokine-mediated apoptosis. Clearly the study of the interaction between UDCA and the GR is still in its infancy; but, considering the clinical safety profile of UDCA, elucidation of the nature of this interaction may lead to the development of more selective and potent GR modifiers that promote the antiinflammatory and immunosuppressive effects of glucocorticoids without the negative biologic effects that so often limit their use.

THERAPEUTIC USE OF URSODEOXYCHOLIC ACID

In humans UDCA is used to treat a variety of chronic hepatopathies, including PBC, primary sclerosing cholangitis, pediatric cholestatic disorders, and intrahepatic cholestasis associated with pregnancy. The largest body of information on the clinical use of UDCA in humans is with PBC. Although most clinical trials with PBC show that UDCA improves serum liver tests and clinical signs, evidence that UDCA inhibits the progression of disease and improves long-term survival is conflicting. However, many studies are limited by the small number of patients; the short duration of treatment; and the long, unpredictable natural course of PBC in humans. More recent evidence suggests that UDCA therapy is most beneficial in early disease.

Following oral administration of UDCA in humans, 30% to 60% is absorbed primarily in the small intestine (80%) with smaller amounts in the colon (20%). Oral absorption is enhanced if the drug is taken with a meal. UDCA has high hepatic first-pass metabolism (70%). Once within hepatocytes, extracted UDCA becomes conjugated to taurine or glycine and then undergoes enterohepatic circulation. The bioavailability of UDCA may decrease with advance cholestasis because of decreased hepatic extraction and increased renal elimination. Thus in patients with severe cholestasis there may be some benefit to higher doses or twice-daily administration of UDCA. In humans UDCA given at 10 to 15 mg/kg/day results in 40% enrichment of bile; higher doses do no better. UDCA is metabolized to lithocholate in the colon and eliminated in the feces. In severe cholestasis renal clearance becomes more prominent. The safety profile of UDCA is outstanding in humans with only limited reports of mild diarrhea. Coadministration with aluminum hydroxide decreases bioavailability. UDCA may increase the bioavailability of lipophilic compounds such as vitamin E or cyclosporine.

There is little information in the literature to guide veterinarians in the proper use of UDCA in small animals. In a dog with chronic hepatitis, UDCA (15 mg/kg/day) resulted in enrichment of UDCA in the serum and was associated with biochemical and clinical improvement (Meyer et al., 1997). Another study has verified the choleretic properties of oral UDCA in healthy dogs (Yanaura and Ishikawa, 1978). Extensive toxicologic studies for Food and Drug Administration approval of UDCA performed in healthy dogs did not reveal any serious side effects of therapy. In normal cats UDCA (10 to 15 mg/kg/day) for 8 to 12 weeks was well tolerated with no changes seen in physical condition, serum liver enzymes, or hepatic histology. Both UDCA and tauroUDCA were detected in the serum of treated cats. A decrease in serum cholesterol was noted in some cats (Nicholson et al., 1996; Day et al., 1994). Anecdotal clinical impressions from veterinary hepatologists who frequently use URSO in feline and canine patients with hepatic disease corroborate these experimental findings. The only side effects reported with any frequency are rare instances of vomiting and diarrhea. In normal dogs and cats oral supplementation of UDCA can increase preprandial and postprandial total serum bile

acids, but typically these increases are not above the reference range

It is currently unknown whether UDCA has any therapeutic benefit in treating canine or feline hepatobiliary disorders. The answer to this question awaits the results of prospective clinical trials. Extrapolation of information generated in the human literature and in experimental models of hepatotoxicity in several species suggests that UDCA should have beneficial effects in dogs and cats as well. The choleric action of UDCA should be beneficial in acute and chronic hepatobiliary disorders marked by cholestasis. In addition, UDCA supplementation may reverse the loss of membrane transport function seen in cholestatic disorders. The possibility of extrahepatic biliary obstruction should always be ruled out before starting therapy because the use of choleric agents is contraindicated in this instance. The long-term hepatoprotective and immunomodulating actions of UDCA should be of benefit in the treatment of chronic inflammatory hepatobiliary disease in both the dog and cat. It is my belief that UDCA is not a panacea for all chronic inflammatory hepatic disorders but may be of some benefit in slowing the progression of disease, especially when used at an early stage. Currently I incorporate UDCA in the therapy of most cases of inflammatory hepatobiliary disease in dogs and cats. In some asymptomatic animals with evidence of hepatobiliary disease discovered serendipitously having increases in serum liver enzymes or when corticosteroids are contraindicated in the therapy (e.g., diabetic animals), I often use UDCA as the only therapy. In addition, appropriate therapeutic measures to manage the complications of hepatobiliary disease (Bonagura, 1995, p. 749) are also instituted. The animals are monitored for 2 to 3 months by following body condition score, appetite, attitude, and the levels of serum hepatobiliary enzymes. If no response is seen during this time, the drug is discontinued or in cases of severe cholestasis the dose is doubled.

There has been some reluctance to use UDCA in the feline hepatic lipidosis (FHL) syndrome because increased bile flux can decrease hepatic production and egress of very low-density lipoproteins. This effect is likely mediated through the binding of bile acids to their nuclear receptor, farnesoid X (FXR). However, bile acids differ in their ability to activate FXR, with UDCA functioning as a very poor ligand. Thus UDCA-induced modification

of the bile acid pool in cats with FHL may actually be beneficial in this regard.

UDCA is available as a 300-mg capsule (Actigal, and also available generically) and a 250- and 500-mg pill (URSO) for oral administration. The two formulations are essentially equivalent, and I do not hesitate to prescribe the generic form since the medication is expensive. The recommended dosage for both dogs and cats, 10 to 15 mg/kg per day orally, is extrapolated from human medicine. The medication is best given with food. There are no known drug interactions between UDCA and other drugs used to treat hepatobiliary disease such as *s*-adenosylmethionine, corticosteroids, azathioprine, vitamin E, or silymarin.

Drug-Associated Liver Disease

MARK E. HITT, Annapolis, Maryland

Drug-associated liver disease (DALD) is a relatively common diagnosis in veterinary practice. It may also be referred to in the human medical literature as drug-induced liver injury (DILI). Hepatotoxicity is the most common clinical pathologic reason for discontinuation or alteration of medication treatment plans.

To recognize DALD, the veterinary clinician must have the possibility of an adverse drug reaction in mind when prescribing any drug. Familiarity of the clinician with the pharmacologic principles of a drug is critical to minimizing risks and early detection of adverse interactions and toxic effects in a specific patient. It is not uncommon for a case with DALD to also involve additional adverse drug reactions to that same product. The liver has many functions in the body, including recognition and detoxification of foreign substances (xenobiotics) and endogenous wastes, recognition and elimination of toxins, manufacturing of substances, storage of metabolic products, metabolic activations, and metabolite eliminations. DALD can develop as the result of a direct effect or consequent to a reactive metabolite of that drug. As practicing veterinarians we are treating ever more complicated medical problems that occur in ever more complex combinations. This leads to increasing numbers of drugs used in situations and in combinations that may not have been anticipated or tested. The more commonly reported drugs associated with liver disease in dogs and cats are listed in Table 131-1. Drugs that are less commonly used in dogs and cats, or that have fewer specific references are included in Box 131-1.

MECHANISMS AND PATHOPHYSIOLOGY

The principle mechanisms of DALD follow the same pathophysiologic mechanisms as those established for many nonpharmaceutical substances that can injure the liver. Hepatotoxins can be drugs, metabolites of drugs, xenobiotics, endogenous toxins, or exogenous toxins. The mechanisms of injury are broadly categorized as *direct* or *idiosyncratic*. DALD events cause dysfunction of liver metabolism or create overt pathology in the liver. If the adverse effect on the liver is considered predictable based on the dose of a medication, it is considered a *direct hepatotoxin*. If the development of liver injury appears random in nature, the pattern is considered to be an *idiosyncratic hepatotoxin*. In this situation it takes hundreds or thousands of uses of the drug in question in true clinical situations to discover a drug's potential for hepatotoxicity. There may be some degree of overlap in how idiosyncratic versus direct reactions are viewed as greater numbers of patients are exposed to a drug. Idiosyncratic DALD remains poorly understood.

Affected individuals may carry a rare combination of genetic and environmental host factors that, if identified, would greatly improve understanding of underlying mechanisms. The role of pharmacogenomics will have important future implications related to our understanding of hepatic drug reactions. One example is the finding of familial lines of herding dogs that are deficient in P-glycoprotein enzymes that limit their metabolism of certain drugs (e.g., azathioprine) through biliary cannicular excretion as one of several mechanisms. Once thousands of doses of medication have been used, a relative prevalence is established even for idiosyncratic DALD events. This information blurs the concept of predictable versus nonpredictable hepatotoxicity.

The liver is in a central position in the body to be exposed to potentially toxic or metabolically stressful situations. Most pharmacologically active substances are lipophilic. Elimination and/or enhancement of positive effect, or of toxicity, is increased by making them more hydrophilic via the phase I and II enzymatic actions of the liver. Metabolism within the liver also depends on oxygen flow via both arterial and portal vessels. Potentially toxic substances can arrive at the liver via ingestion (portal flow) or parenteral administration (arterial delivery). The acinar zones within the hepatic lobules are affected variably by the route of delivery of toxin, the enzymatic concentrations of various metabolic processes in each acinar zone, and the relative degree of oxygenation (or hypoxia) for those zones.

Drugs can be associated with multiple mechanisms of hepatic injury. Hepatic injury can occur via *cytopathic change on hepatocytes* (e.g., hydropic change, lysis, necrosis), *induction of cholestasis* and metabolic dysfunctions, *induction of an immune system* activity against hepatocytes, and/or production of *subsequent proinflammatory responses* to the liver. Adverse hepatic effects of drugs can range from minimal changes in clinical pathologic values to death of the pet.

Overt *cytopathic hepatocellular* injury occurs via damage to cell membranes and injury to mitochondrial energy functions. This results in loss of membrane integrity and is represented by microscopic appearance of hydropic degeneration and necrosis. These changes can also be nonlethal or lethal to the cells. Changes lead to dysfunction of cellular energy systems, leakage of enzymes, retention of irritating wastes (e.g., bile acids), and even initiation of apoptosis. Cell death is furthered by the progressively cascading release of cytokines, superoxide radical formation, and stimulation of inflammatory responses. These inflammatory responses are part of the process of postnecrotic inflammation.

The second major pattern of hepatic toxicity that is seen via histopathology and clinical chemistries is a *cholestatic pattern*. This develops if the effects of the drug

Table 131-1

Drugs More Frequently Associated With Liver Disease in Dogs and Cats

Reported Drugs	Species
Acetaminophen	Dogs and cats
Amiodarone	Dogs
Amoxicillin/Ampicillin products	Dogs and cats
Azathioprine	Dogs
Azithromycin	Cats
CCNU (lomustine)	Dogs
Cephalosporins	Dogs
Cyclosporine	Dogs and cats
Diazepam	Cats
Diethylstilbestrol	Dogs
Enrofloxacin	Dogs
Kava kava	Dogs
Ketoconazole and azole antifungals	Dogs and cats
Glucocorticoids	Dogs (less commonly cats)
Halothane (particularly repeated exposures)	Dogs
Mebendazole	Dogs
Megesterol acetate	Dogs
Methimazole	Dogs and cats
NSAIDs: <i>carprofen may have increased awareness</i>	Dogs and cats
Oxibendazole	Dogs
Phenobarbital	Dogs and cats
Phenytoin	Dogs
Primidone	Dogs
Stanozolol	Cats
Sulfonamides	Dogs
Tetracycline antibiotics	Dogs and cats
Thiacetarsamide	Dogs and cats
Trimethoprim-sulfa combinations	Dogs
Ormetoprim-sulfadiazine	Dogs

NSAID, Nonsteroidal antiinflammatory drug.

to be more intracellular, often resulting in abnormal storage of substrates (e.g., glycogen, bile acids, bilirubin, lipids, and other metabolites) or impaired Golgi complex activities. Stimulation of enzyme production (e.g., alkaline phosphatase, γ -glutamyl transpeptidase) follows.

Mixed patterns also develop in some patients with some drugs. These occurrences may be related to the offending drug, the degree or pattern of necrosis, repetitive exposures, or persistent chronic low-level exposures over time. In some situations, particularly with preexisting genetic make up (certain breed- and sex-related haplotypes), exposure of surface and internal cell membrane antigens may more likely result in formation of protein haptens that act as neoantigens to self. These then trigger autoimmune responses to cell membrane components in biliary epithelium and hepatocytes.

As a cascading series of events, DALD could be seen to include the initial drug-related cell membrane injury and then neoantigen formation via covalent protein binding of drug or drug metabolite, which then creates new adducts from the drug to which the immune system responds. Intracellular inhibition of mitochondrial function and reduced vesicle formation lead to decreased

elimination of toxins, swelling of cells and retention of bile acids, and poor transport or production of bile, which are themselves toxic to hepatocytes. Further cell death is enhanced as apoptosis (programmed cell death) is triggered via Fas pathways and tumor necrosis factor. These also enhance reduced mitochondrial function and subsequent reactive oxygen radicals (superoxide radicals, lipid peroxidation). Fibrosis then may be an end result of postinflammatory stimuli. Some degree of postnecrotic cirrhosis is reported to occur in 30% to 40% of patients that have suffered severe hepatocellular injuries.

The susceptibility of an individual to DALD is affected by multiple factors. First is the drug and its pharmacologic profile. If it is a drug that has a predictable pattern of direct hepatotoxicity, clinicians are more likely to recognize DALD, providing they are familiar with the drug profile. The sex, species, breed, status of organ systems, concurrent disease, nutritional status, age, and concurrent use of other medications also influence the severity of DALD.

CLINICAL PRESENTATION AND DIAGNOSIS

Clinical presentations of DALD are diverse. No specific age, sex, breed, or other signalment would eliminate concern for a DALD. Liver enzyme elevations may be mild to severe. DALD may be discovered incidentally following review of a routine chemistry profile obtained for preanesthetic or geriatric screening. At the other end of the spectrum, a patient may die within days of a drug-induced insult with severe clinical signs. Common recognized symptoms of DALD include nausea, anorexia, vomiting, jaundice, lethargy, and weakness. Less common signs include hepatic encephalopathy, diarrhea, bleeding, increased urination, and other

symptoms of liver disease. Jaundice is not a necessary indicator at the time of presentation. Icterus may only develop late in the course of disease. In most veterinary clinical situations, *acute liver failure* (ALF) is a rare sequela of DALD. However, fatal cases do occur, especially when high or repeated doses of medication have been used without monitoring of the patient. Most often the clinician detects some of the symptoms described previously or monitoring of a serum chemistry profile reveals changes in one or more values: alanine aminotransferase (ALT), alkaline phosphatase (ALP), γ -glutamyltransferase (GGT), or bilirubin. Evaluation should include routine tests such as a complete blood count, platelet count, serum chemistry profile, and urinalyses.

The distinction between liver injury and clinical loss of function is important. In most nonlife-threatening situations, hepatic function remains adequate. Often there is concern for use of drugs that require hepatic metabolism for their activation or that may induce enzyme functions of the liver. There should be a clinical decision as to whether to use another drug, adjust the dose, or avoid these products (e.g., cimetidine, phenobarbital, corticosteroids, enrofloxacin, propranolol). Monitoring of coagulation profiles, and prothrombin time in particular, as a reflection of degree of function for the liver and the possible development of disseminated intravascular coagulopathy is warranted. Use of prothrombin time assay may provide earlier warning of severity of injury. Other common tests used to assess functional hepatic impairment include albumin, blood urea nitrogen, and bilirubin. The clinical first indicators of DALD (at home or in the clinic) can be dark urine, abdominal discomfort, fatigue, anorexia, or nausea.

In veterinary medicine liver injury is often considered significant when values exceed normal reference ranges or increase in comparison to values obtained before the introduction of a drug. In human patients, liver injury is defined by a figure two times the upper limit of ALT or conjugated bilirubin; or by combining results of ALP, GGT, ALT and bilirubin testing, provided that one is greater than twice an upper normal range. Further, clinical pathology changes may appear to be more hepatocellular (predominant ALT) or cholestatic (primarily ALP) in nature. These patterns are not mutually exclusive as mixed or intermediate patterns occur. It is important to recognize that the magnitude of enzyme elevations, even with ALT, is not prognostic for survival. Certainly severe elevations are viewed with more concern in our clinical judgments and actions. But in my experience survival cannot be predicted proportionately to the level of enzyme elevations. Hepatocellular injury is often more defined by ALT elevations. Conceptually a very high value could be caused by the death of a few pockets of hepatocytes with a proportionately large release of enzyme or from large numbers of mildly injured cell membranes that leak a little ALT from each cell. With an acute DALD that is more direct in type, it is not uncommon to see the ALT rise first, followed by the ALP and then bilirubin. The presence of persistent elevations of liver enzymes in the course of chronic drug use (e.g., phenobarbital) requires investigation to prevent progressive damage to the liver. Ascites is not common at the time of initial presentation unless intrahepatic or portal venous thrombosis has occurred.

Routine radiographs of the abdomen should be taken because this remains the primary method of estimating liver size for a given patient. In acute DALD the liver may be swollen, whereas in chronic disease the liver may be atrophied or cirrhotic. Abdominal sonography is now commonly performed to help assess structural changes to the liver. This does not provide specific tissue information, but assists with the formation of the differential diagnoses, clinical assessment, and further treatment and diagnostic plans. Increasing availability of computerized tomography and magnetic resonance imaging may add further insight into determination of types of injury.

Fine-needle aspiration cytology or liver biopsy should only be done if there is a question of diagnosis related to the history or an inconsistent finding with imaging (see Chapter 126). Before invasive testing the patient should be stabilized, and coagulation testing performed. I believe that a buccal (oral) mucosal bleeding time test is very relevant when used in conjunction with the prothrombin time, partial thromboplastin time, and platelet numbers. When activated clotting time is done in a standardized manner, it may also be used to test for a severe coagulopathy.

Diagnosis is often made via the history, symptoms, and supportive findings in clinical pathology. *If a DALD event is suspected, rechallenge of the drug should not be pursued.* The differential diagnostic list for DALD often includes acute leptospirosis, fulminant toxoplasmosis, infectious canine hepatitis, feline infectious peritonitis, per acute Rocky Mountain spotted fever, per acute ehrlichiosis, trauma, septic ascending cholangiohepatitis, *Amanita* (mushroom) poisoning, aflatoxin ingestion, blue/green algae, disseminated intravascular coagulation, unknown drug ingestion, and acute necrotizing pancreatitis. Consideration of the patient's environment, medical history, drug exposures, and previously discussed testing all are needed to make a diagnosis. In some cases the process of elimination results in a "clinical or probable" diagnosis of DALD.

TREATMENT AND MONITORING

When a DALD event is diagnosed, the clinician's judgment determines the degree of intervention required and the need for hospitalization. There should be a strong emphasis on nursing care for patients with DALD. In mild cases removal from the suspect drug is the first and only step required. With moderate-to-severe presentations, emphasis switches to more intensive efforts. The maintenance of microvascular perfusion in the liver is essential. This is done via correction of hypovolemic situations using replacement crystalloid fluids. Assessment of acid base status is part of critical care monitoring; sodium bicarbonate solutions may be used in correction of acidosis. The reader should refer to specific guidelines in acid-base management (see Chapter 10). In severe cases, I place a central venous double-lumen catheter to provide flexibility in treatment and to give partial parenteral nutrition. I commonly use solutions containing 2.5% to 5% dextrose while monitoring blood glucose levels. Monitoring of electrolytes should be routine, and supplementation adjusted as needed, particularly potassium if using dextrose concurrently. If hypoalbuminemia is present, colloid therapy is advised

(e.g., Hetastarch or frozen plasma). Vitamin K₁ is often administered (0.5 to 1 mg/kg q12–24h subcutaneously [SQ]) until coagulation status is clearly established. Nasal oxygen therapy is advised in severe cases to assist with likely hypoxia in the edematous, damaged liver. Glutathione is one of the most potent antioxidant substances on which the liver relies and has been shown to be depleted in cases of liver disease. Administration of thiol and glutathione precursors is advised in moderate-to-severe cases. Some severe situations of acute liver failure (e.g., acetaminophen toxicity) are treated as recommended with *N*-acetylcysteine. The dose is generally started at 140 mg/kg diluted in equal volume of saline and given by slow intravenous infusion. This is followed with 70 mg/kg diluted in saline, slow intravenous infusion, every 6 hours for five to eight treatments or until the patient can be given oral medications. I have found this treatment to be helpful for acetaminophen, thiocetarsamide, amanita, and undetermined and acute nonsteroidal antiinflammatory drug–related DALD. Because sepsis and septic enterotoxic shock are always possible in severely ill patients, coverage with antibiotics is generally advised. Use of intravenous ampicillin (20 mg/kg intravenously [IV] q8h) with enrofloxacin (5 mg/kg IV q24h) or use of ampicillin with sulbactam (10 to 20 mg/kg IV or intramuscularly [IM] q8h) are common initial regimens. Because B vitamins serve as cofactors to many metabolic processes within the liver and they can be depleted rapidly with fluid therapy, it is common to supplement vitamin B-complex preparations via parenteral administration but with no specific guidelines as to dose. I commonly administer 0.01 ml/kg subcutaneously every 24 hours. Prolonged inanition may require parenteral nutritional support. It is likely that 50% of calorie support is more realistic as a goal while the patient is critically ill. When a patient can take oral feedings again, this becomes the preferred route for nutrition and medications. Use of *s*-adenosylmethionine (SAMe) in an oral stable formulation (15 to 20 mg/kg orally [PO] q24h) is advised for support of metabolic function and replenishing glutathione stores (see Chapter 128). It should be given with at least a 2-hour separation from feedings, which may limit its use in some cases. Gastric hyperacidity has been reported to be present in humans with severe liver disease. Use of parenteral antacids initially should be with famotidine (0.5 mg/kg IV, PO, SQ q12h). Use of omeprazole at 0.7 to 1 mg/kg orally can be added as the patient becomes oral. I also introduce ursodiol (8 mg/kg PO q24h) as part of long-term management. Vitamin E (*d*- α -tocopherol) (100 to 400 units per patient per day) is given long term. Use of a well-trusted milk thistle component such as silybin is also thought to be helpful, but no specific dosages are documented for effectiveness in dogs or cats (see Chapter 128).

Management of hepatic encephalopathy (HE) generally is not indicated as part of initial therapy. As a caution, reintroduction of food is often with moderate protein diets until hepatic function is more clearly established. If HE is determined to be present based on clinical signs, standard care with lactulose orally and lactulose and cleansing enemas should be pursued.

If the patient is responding to treatment and withdrawal of the involved drug, the primary indicators may be the patient's vital signs and status. The ALT often decreases 30% to 40% in each 24-hour period; but the ALP and the total bilirubin to a lesser extent may continue to rise as secondary cholestatic effects become manifest. Consistently rising bilirubin without subjective patient improvement is a poor prognostic indicator in human cases of DALD. It may also be prognostic in veterinary medicine since it can suggest secondary fibrosis resulting from inflammatory events and hence partial or complete extrahepatic biliary obstruction or intracellular cholestasis.

Treatment is adjusted constantly via reassessment of the patient and monitoring of laboratory values as warranted to the situation. For a moderately to severely ill patient, it is not uncommon to be hospitalized for 3 to 10 days. As recovery progresses, it remains important to maintain supportive fluids and medications and to retest chemistries, prothrombin time, urinalyses, and blood counts every 24 to 48 hours initially and then spreading out the interval between laboratory testing based on patient assessment. For several months after apparent recovery, it is suggested to monitor these tests and occasionally use paired serum bile acids since post-necrotic cirrhosis can occur. In human medicine some drugs causing DALD (e.g., acetaminophen, dantrolene, isoniazid) have been demonstrated to initiate immune chronic hepatitis, and this may be the case in some veterinary cases as well.

The presentation for DALD is variable. The review of the history, signalment, and environment is critical along with the physical examination in making a diagnosis of DALD. In cases with significant symptoms, aggressive treatment and monitoring are advised. The degree of elevation of liver enzymes, although alarming, is not necessarily predictive of outcome. Aggressive treatment efforts should be pursued, with removal of suspected drugs being the first step. It is advised that the veterinary practitioner faced with a case of DALD review other involved topics dealing with the diagnosis and management of liver diseases in dogs and cats. Some of this information is available in other chapters within this section.

Feline Hepatic Lipidosis

KATHLEEN M. HOLAN, *East Lansing, Michigan*

Feline hepatic lipidosis (HL) is a commonly recognized clinical syndrome observed in debilitated domestic cats. By definition it is the excessive accumulation of lipid within hepatocytes. Ultimately in cats it has the potential to lead to severe hepatic dysfunction and even death. HL occurs either as an idiopathic (primary) condition or secondary to some other primary pathologic process. Development of this disease depends on the establishment of a catabolic state that leads to enhanced mobilization of peripheral fat stores to the liver in conjunction with impaired dissemination of lipid from hepatocytes. The exact physiologic mechanisms that lead to the development of HL are still incompletely understood and are likely multifactorial. A fact that is understood relates to the importance of early recognition along with the prompt initiation of appropriate nutritional therapy. These factors are pivotal to successful management and recovery in the great majority of our affected feline patients.

PATHOPHYSIOLOGY

There are many metabolic and hormonal mechanisms involved in normal feline lipid metabolism. Specifically these mechanisms include those that are responsible for the mobilization of peripheral fat from adipocytes to the liver, as well as those responsible for fatty acid metabolism within the liver and subsequent removal of lipid from hepatocytes. Aspects of protein metabolism unique to obligate carnivores add essential metabolic requirements to overall feline lipid metabolism. The adipocyte, under the influence of hormone-sensitive lipase and lipoprotein lipase and with its ability to contribute to hormonal control of lipid metabolism and appetite control, is increasingly appreciated as an important potential “player” in the development of feline HL syndrome. Prolonged protein malnutrition can have severe consequences, resulting in derangement in all aspects of normal feline lipid metabolism. Systemic oxidative injury, to which cats are particularly susceptible under normal conditions, is also greatly augmented. Better understanding of these mechanisms will undoubtedly improve our ability to treat and prevent HL.

HISTORY AND CLINICAL SIGNS

A majority of cats that develop HL are historically overweight, and most have experienced a period of anorexia before the onset of lipidosis (Barsanti et al., 1977; Center et al., 1993). Although the triggering event for the development of anorexia is often difficult to identify, a complete

review of a cat's recent history may elucidate an acute illness or change in environment sufficient to instigate anorexia and subsequent lipidosis. Cats of any age can develop HL; however, most tend to be middle-aged or older and of either sex. There is no known breed predilection.

Affected cats can present with a variety of clinical signs, including anorexia, depression, weakness, vomiting, ptyalism, diarrhea or constipation, and weight loss. Weakness, depression, and ptyalism may also indicate concurrent hepatic encephalopathy (HE). Physical examination findings often include dehydration, an unkempt coat, icterus, hepatomegaly, and ventriflexion of the neck. Many systemic diseases have been associated with HL in cats, including but not limited to diabetes mellitus, pancreatitis, inflammatory bowel disease, cholangiohepatitis, and various neoplasias. Abnormal physical examination findings related to specific underlying disease processes may also be identified.

DIAGNOSTICS

The purpose of the diagnostic workup in cats with HL is twofold. One is to definitively diagnose the presence of lipidosis within the liver, and the second is to simultaneously rule in or out the presence of an underlying disease process. The diagnostic approach typically begins with a minimum database (complete blood count, biochemical profile, and urine analysis), coagulation profile, diagnostic imaging, and ultimately the procurement of hepatic samples for cytologic and/or histopathologic evaluation. Additional diagnostic tests to help rule out concurrent diseases or as dictated by a patient's clinical status may also be within the initial diagnostic plan. These frequently include a thyroid hormone profile, feline leukemia virus/feline immunodeficiency virus testing, feline pancreatic lipase immunoreactivity (fPLI), and thoracic radiographs.

Blood Work

The complete blood count of a lipidotic cat can be normal or may exhibit changes, including a stress leukogram, nonregenerative anemia, poikilocytosis, or the presence of Heinz bodies. The presence of an inflammatory leukogram should alert the clinician to an underlying disorder. It is important to note that, even if not present initially, anemia, poikilocytosis, and Heinz bodies all have the potential to develop during treatment and therefore warrant close monitoring of the hematocrit.

The biochemical profile of HL patients may reflect a variety of abnormalities as they relate specifically to

cholestasis or to other processes occurring. Common liver enzyme abnormalities include elevated activities of alkaline phosphatase, alanine aminotransferase (ALT), and aspartate aminotransferase. Total bilirubin is usually elevated, and blood urea nitrogen may be normal or decreased. In contrast to other hepatobiliary diseases with a significant necroinflammatory component, HL is not usually associated with elevated γ -glutamyltranspeptidase activity (Center et al., 1986). Hypokalemia, hypochloremia, hypophosphatemia, and hypomagnesemia may be present as the consequence of anorexia or vomiting or may develop during treatment as a result of volume expansion or refeeding. Other biochemical alterations that might be observed include subnormal albumin, increased cholesterol, and hyperglycemia.

The urine analysis of lipidotic cats may reveal lipiduria. An abnormal finding may be bilirubinuria, which precedes the development of hyperbilirubinemia.

Coagulation abnormalities are common in cats with HL. In the largest retrospective study of cats with HL, 45% of cats tested had one or more present (Center et al., 1993). The most common coagulopathy was prolongation of the prothrombin time (PT) as a result of vitamin K deficiency. Vitamin K deficiency in cats with HL can be the result of anorexia, malabsorption caused by severe cholestasis, or decreased production by enteric bacteria secondary to antibiotic therapy. Interestingly, of the 45% of cats with coagulopathies (20 of 44 cats tested) only 3 of 20 had demonstrable bleeding tendencies (Center et al., 1993). This finding underscores the importance of screening for coagulopathies in cats with suspected HL. Hypofibrinogenemia, likely the result of decreased hepatic production, is another coagulopathy noted in cats with HL (Center et al., 1993). Clinical tests available for the assessment of coagulation status include a platelet count, PT, activated partial thromboplastin time (APTT), fibrinogen, fibrin degradation products, and the proteins invoked by vitamin K absence (PIVKA) clotting test (Thrombotest; Nycomed AS). Although PIVKA may be a more sensitive indicator of prolonged clotting times in clinically ill cats, including cats with HL, when compared to PT, APTT, fibrinogen, and thrombocytopenia (Center et al., 2000), it is not readily available in all laboratories. Cats with coagulation abnormalities should be treated with parenteral vitamin K₁ as described later in this chapter.

Liver function tests often considered in cats with HL include measurement of serum bile acids and/or measurement of fasting ammonia levels or tolerance. Most cats with HL are hyperbilirubinemic at the time of presentation, which precludes any additional diagnostic value of measuring serum bile acids. Measurement of serum bile acids may be indicated in the (rare) nonicteric, nonbilirubinuric patient suspected of having HL. Although HE is not a common metabolic consequence of HL, assessment of a fasting ammonia level may be used as a means of diagnosing its presence in cases in which there is a high clinical index of suspicion. However, not all animals with HE have an elevated fasting ammonia level, and there is poor correlation between the degree of elevation of ammonia and clinical HE. Patients with suspected encephalopathy should be fed a protein-restricted diet

such as Prescription Diet k/d (Hill's Pet Nutrition, Inc.) or Feline NF (Nestle Purina PetCare Co.). Lactulose (0.25 to 5 ml q8–12h orally [PO]) should also be administered. The dosage is adjusted until semiformal stools are produced. In moribund patients without enteral access, lactulose can be administered rectally as a retention enema using three parts lactulose to seven parts water. The solution (20 ml/kg q4–6h) should be left in place for 15 to 20 minutes. Antibiotic therapy may also be instituted to help reduce colonic bacteria responsible for ammonia production. Metronidazole (7.5 mg/kg q12h PO), ampicillin (22 mg/kg q8h PO), or neomycin sulfate (20 mg/kg q8–12h PO) can be used to help manage HE. Neomycin sulfate liquid in water (22 mg/kg) can also be used as a retention enema.

Diagnostic Imaging

Abdominal radiography and ultrasonography are commonly used to evaluate the liver and other organs of HL patients. Hepatobiliary scintigraphy and computed tomography are other modalities that have been evaluated for diagnosis of HL, but neither has proven to be clinically reliable. Radiographic changes observed in HL patients can include hepatomegaly and rarely an abdominal effusion. Ultrasonography offers the advantage of examination of other organs associated with diseases that are common predisposing conditions for the development of HL. In addition to the liver, the stomach, intestines, lymph nodes, biliary system, and pancreas can also be evaluated. Ultrasonographically the livers of cats with HL often appear diffusely hyperechoic relative to the falciform fat and may be mildly or moderately enlarged. Careful evaluation of associated organs should always be performed because abnormalities in any of these organs may alter the diagnostic recommendations if more invasive techniques necessitate adequate biopsy sampling.

Fine-Needle Aspiration

Although definitive diagnosis of HL requires histopathologic confirmation, ultrasound-guided fine-needle aspiration of the liver provides cytologic samples that in most cases are adequate for establishing a preliminary diagnosis of HL. Cytologic confirmation of HL is made when a representative sample of liver tissue demonstrates cytosolic vacuolization of at least 50% of the hepatocytes. However, it is important to remember that fine-needle aspiration is not a reliable means of diagnosing inflammatory liver diseases and may miss focal neoplasia. Therefore cytologic diagnosis must always be interpreted with caution and in accordance with hematologic and biochemical and clinical findings. Identification of inflammatory cells or any cells that are not expected hepatic parenchymal cells should prompt recommendation for hepatic biopsy.

Liver Biopsy

As previously stated, the definitive way to diagnose HL is via histopathologic evaluation. Liver biopsy also offers the ability to evaluate hepatic lobular architecture for the presence of inflammatory conditions such as cholangitis or cholangiohepatitis that fine-needle aspiration cannot

determine. However, the clinician must make important clinical considerations before deciding whether to pursue a biopsy. These include the status of the patient, as well as the method used to get a biopsy sample. Because all biopsy procedures require the use of general anesthesia, many cats are not candidates for biopsy at the time of presentation. Existing coagulation abnormalities and metabolic disturbances must be corrected before anesthesia, given the potential for complications during biopsy procedures. Many HL patients must be stabilized for a period of days before they are good anesthetic candidates. For these reasons, along with the relative reliability of fine-needle cytologic findings, not all cats with HL need to have their livers biopsied. Often the decision to do so is reserved for cases that are not improving in response to supportive care or when other suspected diseases are present that warrant biopsy of other organs via laparoscopy or exploratory laparotomy.

TREATMENT

Treatment of HL centers on providing appropriate nutritional support to reverse the catabolic state that has developed while also providing adequate fluid therapy and managing any clinical complications such as vomiting, HE, or bleeding tendencies.

Feeding Methods

Most cats with HL are anorectic at the time of presentation. This almost always necessitates the placement of a feeding tube for enteral nutritional support. Force feeding is one method of delivering nutrition that is tolerated by some cats without the placement of a feeding tube, but in many cases tends to exacerbate preexisting nausea and vomiting. This method frequently does not deliver enough calories to metabolically reverse HL and may also cause a food aversion syndrome that can ultimately lead to a delay in the return to self-alimentation (Center, 2005). In my view this method is only recommended when financial limitations prevent placement of a feeding tube and is *not* an option in vomiting or moribund patients. The types of feeding tubes available for placement include nasogastric, esophagostomy, and gastrostomy tubes. See Bonagura (2000) and Chapter 136 for discussions regarding feeding tubes.

Dietary Considerations

Provision of a high-quality protein diet in amounts that deliver enough energy to reverse the progression of HL is the most important aspect of therapy for feline HL. Diets that derive the majority of their calories from protein or fat are preferable. Many commercially available diets meet these requirements, including Clinicare, Abbott Laboratories; Maximum Calorie, CNM Feline CV formula, Feline Nutritional Recovery Formula, The Iams Co.; and Prescription Diets a/d, m/d, c/d, or p/d, Hill's Pet Nutrition, Inc. The exception to feeding a high-quality protein diet is the encephalopathic patient, in which case this type of diet is contraindicated. In all situations the use of a specifically feline diet is recommended. Diets

formulated for other species often lack essential nutrients required for feline metabolism. If such diets are used, supplementation with taurine (250mg/day) and arginine (250mg/100kcal) is recommended. Cats with pre-existing medical conditions may have dietary limitations that preclude the use of a high-protein diet. Usually these diets suffice during the recovery period and need not be changed.

Although the exact energy requirements for cats with liver disease are not known, there are formulas readily available for calculation of basal and recovery energy requirements. Bonagura (2000) lists these calculations along with feeding regimen recommendations.

Nutritional Supplementation

Over the years a large number of nutritional supplements have been advocated for the treatment of HL in cats. Most have been recommended based on their role in various aspects of lipid metabolism, the urea cycle, or because of their antioxidative effects. Unfortunately there are few controlled studies in cats with HL to either prove or disprove their beneficial effects. Some nutritional supplements appear to have good empiric and/or scientific evidence in cats or other species to imply a potential benefit, while other supplements have been reported to improve survival rates of cats with HL (Center, 2005). It also makes sense in many cases to prescribe other supplements to replace perceived metabolic deficits in patients not consuming adequate calories in spite of lacking scientific evidence. Most are safe when given at recommended dosages and do not potentiate harmful consequences. It must be stated that there is no consensus among clinicians regarding the necessity of nutritional supplementation for cats with HL, and fortunately many of these patients are able to recover and survive without it. Ultimately the decision to use nutritional supplements is often based on clinician experience and supplement availability. In my hospital supplementation tends to depend mainly on clinician preference and experience. B vitamins, including cobalamin, are fairly routinely administered; antioxidant therapy is more variable. Amino acids are supplemented infrequently. Commonly considered supplements are categorized below.

Water-Soluble Vitamins

Anorectic cats are susceptible to depletion of B vitamins, especially thiamine (B_1) and cobalamin (B_{12}). Cats with underlying intestinal disease are especially prone to cobalamin deficiency. The addition of 1 to 2 ml of a fortified B-vitamin complex per liter of crystalloid fluids is recommended for thiamine deficiency. If added, the fluids should be protected from direct light. Plasma cobalamin (B_{12}) levels should be measured in any cat suspected of having HL or underlying intestinal disease. Often cats are given an empiric initial dose of 250 to 500 mcg subcutaneously, with subsequent therapy, if indicated, based on results of plasma levels.

Fat-Soluble Vitamins

Vitamin E (α -tocopherol) is a potent hepatic antioxidant, and depletion of vitamin E is suspected to occur in cats

with HL, thereby lessening the ability of the liver to protect itself against oxidative damage. Although not scientifically proven to be efficacious, dosage ranges between 10 units/kg/day orally and 100 units/cat every 12 hours orally have been recommended.

Vitamin K₁ is administered for treatment of coagulopathies. Dosages of 0.5 to 1.5 mg/kg every 12 hours subcutaneously for three treatments have been shown to be effective in correcting coagulation abnormalities in cats with HL based on PIVKA testing (Center et al., 2005). Because of cholestatic interference with normal absorption, oral administration should be avoided. Excessive or prolonged administration should also be avoided because oxidative injury to organs and red blood cells can ensue. Cats that continue to have coagulation abnormalities despite vitamin K₁ therapy may have more severe hemostatic derangements such as disseminated intravascular coagulopathy and may require transfusions of whole blood or fresh frozen plasma.

Amino Acids

L-carnitine is essential for hepatic lipid metabolism. Studies have suggested that cats with HL may develop a relative deficiency of L-carnitine and that supplementation in cats undergoing weight loss helps to increase fatty acid oxidation and decrease lipid accumulation within hepatocytes. Dosages of 250 to 500 mg per cat per day are recommended. Medical grade L-carnitine has better bioavailability than other commercial products and is recommended over other formulations. Taurine is an essential amino acid for cats, and cats with HL have lower plasma concentrations of taurine than healthy cats. Taurine is important in feline bile acid conjugation, as well as other normal metabolic processes that can become disrupted during the development of HL. A dosage of 250 to 500 mg/day either every 24 hours or divided every 12 hours can be added to the food.

Antioxidants

S-adenosylmethionine (SAME) is essential for the hepatocellular production of glutathione (GSH), and GSH produced in the liver acts as a systemic antioxidant. As a result of protein malnutrition, decreased hepatic levels of SAME and GSH during HL predispose the liver, other organs, and red blood cells to oxidative injury. SAME, at an initial dosage of 35 to 60 mg/kg every 12 to 24 hours or a maintenance dosage of 20 mg/kg every 24 hours, is recommended to help reestablish normal liver GSH levels and prevent the formation of Heinz bodies. Because the bioavailability of SAME is reduced in the presence of food, administration on an empty stomach is preferred. Ursodeoxycholic acid is a hydrophilic bile acid with many beneficial properties, including antiinflammatory and antioxidative effects. Ursodeoxycholic acid promotes bile flow and potentially lessens the noxious effects of more hydrophobic bile acids through alteration of their concentration. Its potential benefit in cats with HL is not known. The use of ursodeoxycholic acid is contraindicated in the presence of any obstruction of biliary outflow. It is well tolerated, and side effects are uncommon. The recommended dosage is 10 to 15 mg/kg every 24 hours.

Fluid Therapy

Cats with HL are usually dehydrated at the time of presentation and require fluid therapy to correct both existing and ongoing fluid losses from vomiting and diarrhea, if present. In most cases, intravenous fluid therapy is the preferred route of administration. Subcutaneous fluids can be administered in mild cases if owner objection because of cost or hospitalization prohibits placement of an indwelling intravenous catheter. Owners can be taught to administer subcutaneous fluids at home, which is helpful in situations in which intravenous fluids are not an option. In general, this method is not advisable for very debilitated patients or patients with profuse vomiting or diarrhea. A balanced, polyionic crystalloid fluid such as Ringer's or lactated Ringer's solution is recommended for initial support. In cases of severe HL, concern regarding the inability of the liver to properly metabolize lactate may make solutions without lactate a better choice if available. Dextrose-containing fluids should be avoided since carbohydrates tend to promote hepatic triglyceride accumulation, inhibit hepatocellular fatty acid oxidation, and may exacerbate hypokalemia and hypophosphatemia via insulin stimulation.

Electrolyte Therapy

Electrolyte imbalances are often identified in HL patients at the time of presentation or may develop during treatment as a result of fluid therapy or refeeding. Hypokalemia is the most common electrolyte abnormality in cats with HL and is significantly associated with failure to survive (Center et al., 1993). Lethargy, muscle weakness, ventriflexion of the neck, intestinal stasis, myocardial depression, and inability to concentrate urine can all start to develop when serum K⁺ is 2.5 mEq/L or less. Supplementation in the form of potassium chloride (KCl) is added to the fluids. The amount of K⁺ added to fluids depends mostly on the initial serum levels and the rate of administration of the intravenous fluids. The rate of administration of KCl should never exceed 0.5 mEq/kg/hour. Initially serum potassium levels should be monitored twice daily to ensure adequate supplementation, especially as refeeding begins. Serum potassium levels can worsen as a consequence of the insulin-mediated intracellular shift that occurs in response to alimentation and may necessitate more aggressive supplementation. Persistent hypokalemia in the face of otherwise appropriate therapy may be the result of concurrent hypomagnesemia and warrants assessment of serum magnesium levels. Hypomagnesemia-induced hypokalemia will not resolve until the hypomagnesemia is corrected. Magnesium is an important enzyme cofactor, and low serum levels can cause muscle weakness manifesting in many of the same clinical signs observed with hypokalemia and hypophosphatemia. Supplementation is in the form of intravenous administration of either magnesium sulfate or magnesium chloride, which are packaged as 50% solutions. They should be administered as 20% solutions in 5% dextrose and water (D₅W). An initial starting dosage of 0.75 to 1 mEq/kg/day continuous-rate infusion (CRI) is given the first day, after which the dosage is lowered to 0.3

to 0.5 mEq/kg/day for another 2 to 5 days. Serum levels should be monitored daily. Overdoses are treated with calcium gluconate given intravenously at a 50-mg bolus followed by a 10 mg/kg/hour CRI.

Hypophosphatemia is a potentially serious electrolyte abnormality that may be evident at the time of presentation or more likely develop as a result of refeeding. Cats with HL may be hypophosphatemic from low intake, decreased intestinal absorption, or increased renal loss. With the introduction of food, stimulation of insulin secretion promotes intracellular uptake of phosphorus and glucose, further lowering serum levels within 12 to 72 hours of the commencement of feeding (Justin and Hohenhaus, 1995). Manifestations of hypophosphatemia can include muscle weakness, hemolytic anemia, leukocyte dysfunction, platelet dysfunction, and decreased tissue oxygenation as a result of decreased levels of 2,3-diphosphoglycerate. Phosphorus is supplemented when serum levels fall below 2 mg/dl. Intravenous administration of either potassium phosphate or sodium phosphate is recommended at 0.01 to 0.06 mmol/kg/hour. These need to be given in calcium-free solutions to prevent precipitation of calcium phosphate. If potassium phosphate is used, the potassium content needs to be taken into consideration when calculating overall potassium supplementation. During treatment, serum phosphorus and calcium levels should be monitored twice daily since hypocalcemia can be a consequence of intravenous phosphate therapy (Adams et al., 1993). Once phosphorus levels are above 2 mg/dl, the intravenous dosage can be reduced by 50% and tapered off shortly thereafter. Oral supplementation can continue until serum levels are within the normal range. The recommended oral dosage is 0.5 to 2 mmol/kg/day. Skim milk or commercial phosphate supplements can be offered orally or provided through a feeding tube. For patients with lactose intolerance, use of lactose-free products divided into multiple small servings can help prevent diarrhea from occurring. Phosphorus supplementation should always be closely monitored, especially in patients with concurrent renal disease. It is not recommended in cats that are oliguric or hypercalcemic (Griffin, 2000). Phosphate binders such as aluminum hydroxide or sucralate should not be used in patients with low phosphorus levels.

Hypocalcemia, if present, may be secondary to acute pancreatitis or may develop as a result of phosphorus supplementation. This is an uncommon finding, and treatment usually is not necessary unless clinical signs of deficiency develop.

Additional Therapeutic Considerations

Control of Vomiting

Vomiting is a common clinical problem in cats with HL. Causes include electrolyte imbalances, gastric and intestinal stasis, excessive feeding, feeding tube complications, liver dysfunction, or underlying diseases such as inflammatory bowel disease or pancreatitis. The use of antiemetics is often necessary in the initial management of HL. However, in conjunction with antiemetic therapy, the clinician should always be sure to reevaluate aspects of intestinal health, as well as feeding and feeding tube

issues. Constipation is a common sequela of dehydration, and evacuation of impacted fecal material can help to establish normal intestinal motility. Feeding tubes should be evaluated for any signs of irritation or infection at the site of placement. Concerns regarding tube placement or possible kinking can be addressed with radiography and are enhanced with the administration of a radiopaque iodinated contrast solution into the tube. Cats with HL frequently have gastric atony from prolonged anorexia, and even small meals can induce vomiting as a result of gastric distension. Alternatively many cats do very well initially, with food delivered as a CRI. This is best accomplished by providing a liquefied diet via an intravenous fluid line that is attached to the feeding tube. Fluid or syringe pumps are used to deliver a specified number of milliliters per hour. This method tends not to overdistend the stomach and is well tolerated. The rate of delivery of food can be increased slowly over a period of days to ensure tolerance while the frequency of vomiting is diminished. Once this is accomplished, a transition to individual meals can be made.

Despite these considerations, many cats still require medical antiemetic therapy. Metoclopramide is usually the initial drug of choice and can either be administered in fluids as a CRI (0.01 to 0.02 mg/kg/hour or 1 to 2 mg/kg/day) or given subcutaneously (0.2 to 0.5 mg/kg q8h SQ 30 minutes before feeding a meal). Metoclopramide has antiemetic and prokinetic effects, both of which are beneficial in HL patients. In cases in which vomiting is not controlled with metoclopramide, use of ondansetron (Zofran, Glaxo Wellcome; 0.1 mg/kg q12–24h PO or 0.1 to 0.3 mg/kg q8–12h intravenously [IV]) or dolasetron (Anzemet, Hoechst Marion Russel; 0.5 mg/kg q24h PO, SQ, IV) is usually effective. In my opinion these are the second antiemetics of choice. My hospital frequently uses dolasetron because of its decreased frequency of administration. These drugs are relatively expensive, which may prohibit their use. Phenothiazine derivatives are associated with marked side effects and are contraindicated in patients with hepatic insufficiency. Their use is not recommended in cats with HL.

Promotility agents are often used in HL patients, especially when significant gastric and intestinal stasis is suspected. As mentioned, metoclopramide at recommended dosages offers the advantage of promoting gastric emptying in addition to its antiemetic effects. For many cats this therapy alone is enough. Additional benefit, if needed, may be gained by the addition of cisapride to the treatment regimen. Cisapride (0.1 to 0.5 mg/kg q8–12h PO) is a more potent stimulator of intestinal motility than metoclopramide and can be helpful in patients that are refractory to metoclopramide or in those that have not produced a bowel movement despite several days of significant alimentation. Ranitidine (Zantac, Glaxo Wellcome), an H_2 receptor antagonist with some prokinetic activity may also be considered (0.5 to 2 mg/kg q8–12h PO, IV) but in my experience is not as effective as cisapride for increasing intestinal motility.

H_2 receptor blockers decrease gastric acid production and are considered beneficial because of their ability to help alleviate the symptoms of gastritis or gastric ulceration that can be associated with liver disease and inflam-

matory bowel disease. Famotidine (Pepcid, Merck Sharp Dohme), cimetidine (Tagamet, Smith Kline French), nizatidine (Axiid, Eli Lilly), and ranitidine are options. Famotidine (0.5 to 1 mg/kg q12–24hr, PO, IV) is the most common H₂ receptor blocker used in our hospital. Advantages include once-daily dosing and the fact that it does not affect hepatic P-450 enzymes. Cimetidine should be avoided because of its effect on the hepatic P-450 enzymes.

Antibiotic Therapy

Prophylactic antibiotic therapy for HL is not recommended. However, complications might arise that warrant their use. These can include development of bacterial infections either at the site of the feeding tube or intravenous catheter placement or the presence of HE, discussed earlier in this chapter. Appropriate antibiotic therapy should be based on culture and sensitivity results whenever possible; otherwise broad-spectrum antimicrobial coverage should be considered. Tetracyclines should not be used in cats with HL because of their untoward effects on hepatocellular metabolism (Center, 2005).

Appetite Stimulation

For many reasons the use of appetite stimulants to encourage self-alimentation in cats with HL is not advised. Many of the commonly recommended drugs, including diazepam, oxazepam, clonazepam, and cypheptadine, require hepatic metabolism and have been associated with hepatic failure. Benzodiazepines may act to activate the γ -aminobutyric acid/benzodiazepine receptor system, a theorized factor in the pathogenesis of HE. For reasons discussed in the following paragraph, propofol should also not be used for appetite stimulation in cats with HL.

Drugs Not Recommended

In general, steroids are not recommended for treatment of HL. Glucocorticoids are catabolic and can interfere with normal hepatocellular lipid metabolism. Stanozolol (Winstrol R, Winthrop), an anabolic steroid occasionally prescribed for use in cats, has been shown to produce hepatotoxicity (Harkin et al., 2000). Any drugs that are associated with increased risk of oxidative injury should also be avoided. In cats these include products with propylene glycol carriers and benzene derivatives. Vitamin K₁ therapy can be associated with the development of Heinz bodies and resultant hemolytic reactions that can occur with either excessive or prolonged dosing. Propofol toxicity can develop in cats with HL. Although the exact causes for this are not completely understood, proposed mechanisms include

an inability to properly metabolize the phenol component of the drug, as well as impaired mitochondrial fatty acid oxidation, a syndrome observed in critical human pediatric patients (Center, 2005).

MONITORING

The amount of monitoring necessary for successful management of cats with HL is somewhat case dependent. Cats that are not extremely debilitated or exhibit few complications at the time of presentation or cats that begin eating shortly after supportive measures have begun may not require a large degree of intensive monitoring before they are able to be managed at home. Others require intensive monitoring of their electrolytes, hematocrit, and coagulation status for many days before and after the placement of a feeding tube. Once a cat has been stabilized and a feeding tube placed, the immediate 72 hours tend to be the most critical time for the development of life-threatening electrolyte disturbances as a result of refeeding. After that, periodic checks of liver parameters, including total bilirubin, serum alkaline phosphatase, and ALT, are helpful to establish either a trend toward normalization or to raise suspicion for the need for further diagnostics. If metabolic imbalances can be managed and vomiting controlled, most cats are able to make a full recovery within weeks.

Feline Inflammatory Liver Disease

DAVID C. TWEDT, *Fort Collins, Colorado*

P. JANE ARMSTRONG, *St. Paul, Minnesota*

Liver disease is a common clinical finding in the cat. The disorders described are most frequently hepatic lipidosis, chronic inflammatory disease, neoplasia, and hepatocellular necrosis (such as toxic or drug-related conditions). This chapter covers only the common inflammatory disorders. Based on a 10-year retrospective study of feline liver biopsy data from the University of Minnesota, inflammatory liver disease is the second most common category of liver disease in cats in the United States after hepatic lipidosis (Gagne, Weiss, and Armstrong, 1996). A smaller study at Colorado State University identified a similar prevalence of lipidosis followed by inflammatory liver disease in cats having total bilirubin concentrations greater than 3 mg/dl.

THE CHOLANGITIS COMPLEX

Inflammatory liver disease in cats is confusing with regard to both nomenclature and pathologic grouping of histologic lesions. The lack of consistency in terminology has hindered our ability to clarify the clinical syndromes as to the etiology, therapy, and prognosis for the various subtypes of this disorder. Recently the World Small Animal Veterinary Association (WSAVA) sponsored an international group of pathologists and clinicians given the charge to standardize the histologic classifications of small animal liver disease. The WSAVA Liver Standardization Group now proposes a simplified classification scheme for the different types of inflammatory liver disease in cats (van den Ingh et al., 2006). Collectively inflammatory liver diseases were grouped into different types of cholangitis (Box 133-1). The WSAVA Liver Standardization Group further recommends that the term *cholangitis* be used in preference to *cholangiohepatitis* in cats because, unlike in dogs, the primary inflammatory changes are centered on or surrounding bile ducts. In some cases of feline cholangitis, the inflammatory changes may extend into and involve the hepatic parenchyma; this has previously been referred to as *cholangiohepatitis*. It should be noted that primary chronic inflammatory parenchymal disease, unrelated to specific infectious diseases such as feline infectious peritonitis or toxoplasmosis, is rare in cats. This is in contrast to dogs, in which chronic hepatitis represents the major class of inflammatory liver disease diagnosed. Disruption of the limiting plate of the portal triad with extension of inflammation into hepatic parenchyma is not considered to be a consistent feature of the feline cholangitis syndrome.

The WSAVA Liver Standardization Group recognizes three distinct forms of cholangitis in cats: neutrophilic,

lymphocytic, and cholangitis associated with liver flukes. However, the reader should be aware that in the cholangitis complex there is considerable overlap of the clinical syndromes. The neutrophilic form of cholangitis can also be clinically and pathologically subdivided into an acute neutrophilic form (ANF) and a chronic (and less suppurative) neutrophilic form (CNF). These two subclassifications are thought to likely represent different stages of a single disease process. Lymphocytic cholangitis and cholangitis associated with liver flukes are also discussed but appear to be less common in occurrence. A separate entity, referred to as lymphocytic portal hepatitis, is usually mild and may represent a nonspecific reactive or aging change. However, in some cats it can be associated with clinical and/or biochemical signs of liver disease. It remains an unanswered question as to whether lymphocytic portal hepatitis is a distinct clinical syndrome or simply a common histologic lesion found in many older cats.

NEUTROPHILIC CHOLANGITIS

Neutrophilic cholangitis, previously referred to as suppurative or exudative cholangitis/cholangiohepatitis, is the most common type of biliary tract disease observed in cats in North America. Neutrophilic cholangitis is thought to be the result of biliary tract infection ascending from the gastrointestinal tract. In the ANF, the lesions are exclusively neutrophilic or suppurative, but over time it is thought that cases may progress to a CNF having a mixed inflammatory pattern containing variable numbers of neutrophils, lymphocytes, and plasma cells.

Acute Neutrophilic Form

In the ANF of cholangitis, neutrophilic inflammation is centered on the bile ducts. Enteric bacteria, most often *Escherichia coli*, may be cultured from either the bile or liver. Other bacterial isolates reported in affected cases have included *Enterococcus* spp., *Bacteroides* spp., *Clostridia* spp., *Staphylococcus*, and α -hemolytic *Streptococcus*. Preliminary investigations using culture-independent methods have also resulted in identification of deoxyribonucleic acid (DNA) sequences of *Helicobacter* spp. from a few cats with inflammatory liver disease (both ANF and CNF). These DNA sequences were enteric *Helicobacter* spp. but distinct from the reported gastric species found in cats. Further support for the enteric bacteria theory of pathogenesis comes from unpublished data that the author (DT) obtained. Enteric bacteria were observed in or around bile ducts in approximately 25% of cats that

Box 133-1

Classification of Feline Inflammatory Liver Disease

- Neutrophilic cholangitis
 - Acute neutrophilic form
 - Chronic neutrophilic form
- Lymphocytic cholangitis
- Cholangitis associated with liver flukes
- Lymphocytic portal hepatitis

had histologic evidence of cholangitis and were examined using a fluorescence in situ hybridization (FISH) assay. Some cats affected with cholangitis may also have related diseases, most often pancreatitis and inflammatory bowel disease (IBD). Since cats normally have high enteric bacterial concentrations in the upper gastrointestinal tract, it is speculated that, when concurrent IBD is present, the inflammation may alter distal common bile duct function or perhaps the vomiting from the IBD causes intestinal pressure changes predisposing to ascending bacterial infections. Anatomic abnormalities of the gallbladder or common bile duct or the formation of choleliths may also predispose cats to cholangitis.

The classical histologic description of the ANF of cholangitis is neutrophils within the walls and lumen of biliary ducts and surrounding the portal areas. Sometimes bacteria can be seen in the bile duct lumen or walls. There is bile duct epithelial degeneration and necrosis. Inflammation can also extend through the limiting plate to involve the periportal hepatic parenchyma. The intrahepatic and extrahepatic bile ducts may become dilated, but usually there is minimal biliary hyperplasia or periductal fibrosis in the acute cases. In some very acute conditions, inflammation may be confined to the larger bile ducts, with the gallbladder and hepatic parenchyma spared.

Clinical Findings

This disorder is observed primarily in young-to-middle-aged male cats (generally 3 to 5 years of age). Most cats present because of acute illness of one or several weeks' duration. Common clinical signs include acute vomiting, diarrhea, anorexia, and lethargy. Vomiting appears to be a very consistent clinical sign in most cats with biliary tract disease. Physical examination often reveals a fever, dehydration, icterus, abdominal pain or discomfort on cranial abdominal palpation, and hepatomegaly (<50% of cases). Laboratory findings with all types of cholangitis are quite variable, and the ANF of cholangitis is no exception. A mild-to-moderate leukocytosis is common in most cats having a fever. Typically there are mild-to-moderate increases in serum activities of alanine aminotransferase (ALT), alkaline phosphatase (ALP), γ -glutamyltransferase (GGT), total bilirubin, and bile acids. Because the inflammation is centered on bile ducts, increases in the cholestatic enzymes (GGT and ALP) are expected. Early in the course of disease, inflammation may be limited to the larger bile ducts or gallbladder sparing the liver resulting in normal liver enzymes. In these cases there is also often

minimal if any histologic change in the liver parenchyma. Rarely we have observed peracute cases of cholangitis in which only the total bilirubin was elevated. Inspissation of the bile is common in neutrophilic cholangitis and may cause partial or complete obstruction of the common or intrahepatic bile ducts.

Routine abdominal radiographs are rarely helpful in making a diagnosis, but ultrasound can be rewarding. Changes in bile ducts may sometimes be observed in the ANF. Ultrasonographic changes may include gallbladder or bile duct distention, cholelithiasis, cholecystitis, or sludging (hyperechoic) material in the biliary system. The bile ducts and gallbladder also may be thickened because of edema and inflammation. Occasionally biliary obstruction occurs. It is suggested by a dilated gallbladder and tortuous bile ducts and a common bile duct diameter of greater than 5 mm.

Definitive diagnosis requires a liver biopsy and/or biliary cytology and culture, but a tentative diagnosis is often made based on the clinical and laboratory findings coupled with a response to appropriate antibiotic therapy. Cytologic examination of fine-needle liver aspirates that shows suppurative inflammation helps support the diagnosis. It is important to be aware that liver aspirate cytology often has a poor correlation with histopathology. This is particularly a concern when peripheral neutrophilia is present and the inevitable blood contamination of the liver aspirate may be difficult to distinguish from neutrophilic inflammation in the liver. Whenever possible, a 22-gauge ultrasound-guided gallbladder aspirate for bile cytology and culture should also be performed. Bile aspirates are relatively safe if the needle is directed through the right medial liver lobe and into the gallbladder lumen. With this approach, any bile leakage drains back into the liver and not into the peritoneal cavity. Suppurative inflammation and bacteria may be observed in the bile cytology and is diagnostic for the ANF of cholangitis.

If a liver biopsy is performed, hepatic tissue should always be cultured for aerobic and anaerobic bacteria. Techniques for biopsy include ultrasound-guided needle biopsy, laparoscopy, or laparotomy. The latter two techniques also make it possible to examine the extrahepatic biliary system, pancreas, and other intraabdominal structures.

Treatment

The ANF of cholangitis requires prompt initiation of antibiotic therapy, ideally based on culture and sensitivity. If cultures are negative or empiric antibiotic selection becomes necessary, the clinician must make an educated guess as to an appropriate antibiotic to use based on the most common bacterial isolates from bile (Wagner, Hartmann, Trepanier, 2007). We suggest selecting an antibiotic that is effective against most enteric gram-negative aerobes and that has good hepatic and biliary penetration. We prefer cephalosporins, amoxicillin, or amoxicillin-clavulanic acid but some cases will require a fluoroquinolone. We recommend that cats be treated for at least 4 weeks even though most cats improve in approximately a week with appropriate antibiotics. Others suggest that an even longer duration of therapy (2 months or longer) is required to prevent relapse, but this has not been documented. Additional management includes appropriate fluid and electrolyte replacement.

Ensuring adequate intake of a high-energy, high-protein diet is a priority throughout treatment. Nutritional support, often by short-term use of a nasoesophageal tube, may be indicated in the anorexic cat because it is important to prevent the development of concurrent hepatic lipidosis. Protein restriction is rarely needed because it is unusual for biliary tract disease to result in sufficient parenchymal damage to cause encephalopathy. Protein is an important nutrient for liver repair and regeneration and should not be restricted unless hepatic encephalopathy is present.

Hepatobiliary disease can be painful, and pain management is indicated in these cases. Most acute pain control can be accomplished through the use of drugs such as hydromorphone or buprenorphine (the latter drug can be administered sublingually and is absorbed through the buccal mucous membranes). Meperidine or butorphanol can also be used, and for longer-duration pain control, a fentanyl patch is very effective.

Surgical therapy is uncommon but may be required for cholelith removal or bile duct decompression if biliary obstruction is present. Occasionally the bile becomes the consistency of a thick sludge to the point of obstruction, and this requires vigorous flushing of the extrahepatic biliary system. This is best accomplished by opening the gallbladder and flushing antegrade down the common bile duct. Sometimes it is also necessary to open the duodenum and flush retrograde from the duodenal papilla as well. We advise preserving the normal biliary anatomy and avoiding biliary bypass surgical techniques (cholecystoduodenostomy or cholecystojejunostomy) whenever possible. These surgical procedures should be performed only when necessary because they are often associated with chronic postoperative problems.

We believe that ursodeoxycholic acid (Actigall, Novartis, 10 to 15 mg/kg q24h orally [PO]) should be used in cats with cholangitis. This drug has been shown to have many positive benefits in cholestatic biliary tract disease in other species. Among its effects include amelioration of damage to cell membranes caused by retained toxic bile acids. Ursodeoxycholic acid improves biliary secretion of bile acids, may improve bile flow (choleresis), and has immunomodulatory properties that may reduce immune-mediated liver damage. Studies in cats have found minimal-to-no toxicity. Some clinicians avoid its use when there is the slightest potential for bile duct obstruction, fearing that ursodeoxycholic acid could make the damage worse or even potentiate rupture of the ducts or gallbladder from the choleretic action of the drug. This theory is unfounded and not supported in experimental studies. For example, one study in rats with surgical obstruction of the common bile duct treated with either placebo or ursodeoxycholic acid found that the ursodeoxycholic acid treated rats had less hepatocellular damage than the placebo group showing a protective effect (Frezza et al., 1993). However, if an obstruction is identified in a cat with cholestatic liver disease, surgery would be indicated.

Chronic Neutrophilic Form

The ANF of cholangitis is thought to progress in some cats to a more chronic form, but the time frame and factors for this progression are unknown. The condition has also been referred to as nonsuppurative or lymphocytic-

plasmacytic cholangitis. In the CNF of cholangitis there is mild-to-marked infiltration of portal areas by plasma cells and lymphocytes with a variable number of neutrophils. As with the ANF, the inflammation is centered on the bile duct walls, and inflammatory cells may be observed within the bile duct lumen. Inflammation is associated with biliary epithelial degeneration and necrosis. The inflammatory process may also extend through the limiting plate to involve parenchyma. Biliary hyperplasia, a sign of chronicity, is common, and occasionally periductal (sclerosing) fibrosis and bridging fibrosis may develop. In very rare cases biliary cirrhosis can develop, resulting in liver failure.

The etiology for the CNF is unknown, but it is thought by some to be caused by persistent inflammation initiated by an inciting bacterial etiology. As mentioned previously, many enteric bacteria, *Helicobacter* spp., and even *Bartonella* spp. have been implicated as potential etiologic agents. Our yet unpublished study found enteric bacteria using a FISH assay in the biliary epithelium in some cats with the CNF of cholangitis that were cultured negative. Others have postulated immune-mediated mechanisms as factors for the chronic form, possibly triggered by persistent infection or inflammation.

It has been observed that many cats with cholangitis also have concurrent chronic pancreatitis and IBD. This is supported by a study that found that 83% of affected cats with chronic biliary tract disease also had histologic evidence of IBD and 50% had concurrent chronic pancreatitis (Gagne et al., 1999). The association of concurrent inflammation in the three different organs has been referred to as the *feline triaditis syndrome*. In most cases the IBD and pancreatitis are rather mild. When pancreatitis is present, it is generally chronic and described predominantly as ductal inflammation and fibrosis. Possibly the common channel theory, whereby the pancreatic ducts and bile ducts join as a common duct before entering the duodenum, may explain the relationship of biliary tract disease and chronic pancreatitis, whereby ascending bacterial infections in the biliary system are likely to involve the pancreatic ducts as well.

Clinical Findings

Cats having the chronic form of cholangitis tend to be older than those with the ANF at the time of the diagnosis. The clinical signs are often intermittent and can include vomiting, lethargy, anorexia, and weight loss. The signs often tend to wax and wane over months. The membranes on examination may be icteric; this is most easily observed in the sclera and hard palate. Laboratory abnormalities are quite variable. A leukocytosis is uncommon; but most cases have increases in GGT, ALP, total bilirubin, and bile acids, with variable increases in ALT and alanine aspartate aminotransferase. Ultrasound evaluation in cats with the CNF of cholangitis may show changes similar to those in the more acute cases. As fibrosis and bile duct replication take place, the portal areas become more hyperechoic, and the bile ducts can become more torturous. Because of the association with chronic pancreatitis and IBD, both of these organs should also be carefully examined. Chronic pancreatitis usually appears as a nodular irregular organ. Increases in serum amylase

and lipase activities do not correlate with the diagnosis of pancreatitis in cats. Feline pancreatic lipase immunoreactivity concentration may be abnormal with concurrent ongoing chronic pancreatitis, and it is the better laboratory test to support the diagnosis of chronic pancreatitis.

A definitive diagnosis of the CNF of cholangitis requires a liver biopsy and possibly a gallbladder aspirate. Fine-needle hepatic aspirates with cytology are less helpful in making the diagnosis of this more chronic and less suppurative form. Liver biopsy tissue and bile should always be cultured for aerobes and anaerobes. When laparoscopic or surgical biopsies are performed, the pancreas and intestine should be evaluated and possibly biopsied.

Treatment

Since the etiology of the CNF of cholangitis is unknown, the role of bacteria in this condition is unclear, and no reported studies investigating therapy are available. This makes definitive therapeutic recommendations difficult to provide. We believe that an appropriate course of antibiotic therapy as described with the ANF of cholangitis is indicated, with or without a positive culture. The duration of therapy should extend for several weeks if not longer. If the biopsy sections contain relatively few neutrophils with a predominance of lymphocytic and plasmacytic inflammation, a combination of antimicrobial and corticosteroid therapy is often used, either concurrently with the antimicrobial therapy or starting after about 2 weeks of antibiotic therapy. Corticosteroids are given to control the inflammatory component of the disease. Alternatively corticosteroids may be added if cats fail to respond to antibiotic therapy after several weeks of therapy. A dosage of 1 to 2 mg/kg every 24 hours orally of prednisolone is used initially. If successful in improving clinical signs and biochemical changes, the dosage is slowly tapered to an alternate-day dose for long-term maintenance. A schedule commonly used is to start therapy at 1 mg/kg every 12 hours for 2 weeks and then progressively reduce the dosage to 1 mg/kg every 24 hours for 2 weeks, 0.5 mg/kg every 24 hours for 2 weeks, and finally 0.5 mg/kg every 48 hours for 4 weeks. Biochemical values and clinical response should be monitored before each reduction in dosage. If the clinical and biochemical responses are satisfactory, dosages as low as 0.5 mg/kg every 48 hours may be sufficient if long-term maintenance is required. Ideally treatment decisions would be based on repeat liver biopsies. Long-term corticosteroid treatment is tolerated well by most cats, and side effects are usually minimal. There are no reported studies using other types of immunosuppressive therapy. An additional therapeutic strategy includes dietary manipulation for documented or presumed concurrent IBD. It should be noted that corticosteroid therapy is not contraindicated in cats having current chronic pancreatitis and may actually be beneficial for the same reasons mentioned earlier.

If coagulation abnormalities are present, administer vitamin K₁ (0.5 to 1.5 mg q12h SQ or IM) (using a 25-gauge needle) for two doses and monitor coagulation profiles. Hepatic encephalopathy appears to be relatively uncommon in cats with acquired liver disease and is manifested most frequently by excessive salivation. Hepatic encephalopathy can be managed by giving lactulose orally (0.5 to 1 ml/kg q8h PO) with or without addition of enteric

antibiotics (neomycin 20 mg/kg q8–12h PO). Anorexia must be managed promptly to prevent further deterioration in clinical condition and possible development of concurrent hepatic lipidosis. Assisted oral feeding should be attempted for 12 to 24 hours following beginning of therapy; after which, if the patient has inadequate food intake, a nasoesophageal, esophagostomy, or gastrotomy feeding tube should be placed. Ensuring adequate intake of a high-energy, high-protein diet is a high priority throughout treatment.

There is increasing interest in the use of nutraceuticals in the treatment of feline liver disease. They are generally given for their antioxidant effects. At this time controlled clinical trials are lacking, but their widespread use likely reflects clinician frustration in treating many forms of liver disease and the belief that they are relatively safe. Oxidative damage from free radical formation is one potential mechanism of cellular damage in liver disease. High concentrations of bile acids, accumulation of heavy metals, and inflammation cause free radical generation in the liver. Vitamin E and SAME are commonly used; vitamin C and phosphatidylcholine may also be considered. The herb milk thistle has also recently attracted both human and veterinary attention for its reported hepatoprotective effects. Clinical trials on its use in veterinary patients have not yet been published. The author (DT) has studied pharmacokinetic properties of silybin (a potent isomer of milk thistle) and identified no toxicity in the cats studied. When bound to phosphatidylcholine, silybin improves drug absorption. A suggested dosage for silybin-phosphatidylcholine (Marin, Nutramax Labs) is 5 mg/kg every 24 hours orally.

LYMPHOCYTIC CHOLANGITIS

Lymphocytic cholangitis (severe lymphocytic portal hepatitis, progressive lymphocytic cholangitis, or non-suppurative cholangitis) is described as a very chronic inflammatory biliary tract condition that progresses over months and years. This disorder appears to be more common in European than in North American cats and has many similarities to primary biliary cirrhosis in humans. The pathology of the liver is characterized by a consistent moderate-to-marked infiltration of small lymphocytes predominantly restricted to the portal areas, often associated with variable portal fibrosis and biliary proliferation. The lymphocytic infiltrates are centered on, and may infiltrate into, the walls of the bile ducts, but occasionally infiltrates extend into the hepatic parenchyma. There may be lymphoid aggregates, obliteration of bile ducts, bile duct dilation and biliary hyperplasia, and fibrosis or bridging portal fibrosis. A few plasma cells and eosinophils may be scattered in the portal areas. The chronic stage is characterized by predominant monolobular fibrosis, but with this there is also a reduction in the intensity of lymphocytic infiltration. This later stage results in considerable distortion of liver architecture. The bile ducts can also become irregular with dilation and fibrosis. In some cases, lymphocytic infiltrates in the portal areas may be confused with well-differentiated lymphocytic lymphoma.

It is postulated that lymphocytic cholangitis could be the result of immune-mediated mechanisms based on pre-

liminary immunologic studies, whereas Boomkens (2004) found DNA fragments of *Helicobacter pylori* in the bile of some cats, suggesting bacterial involvement in the pathogenesis of the disease. Recently *Helicobacter* spp. have also been implicated in human primary sclerosing cholangitis and primary biliary cirrhosis.

The European studies describe this condition as a slowly progressive chronic disease continuing over months and years. It is often first identified in cats under 4 years of age; and Persian cats appear to be overrepresented, suggesting a possible genetic predisposition. The most common clinical features observed late in the disease include ascites, jaundice, and hypergammaglobulinemia (in almost all cases). The elevation in globulins reflects ongoing chronic inflammatory changes but could lead the clinician to consider FIP or other differentials for hypergammaglobulinemia. Fever is generally not a feature of the disease. Cats with lymphocytic cholangitis initially present because of chronic weight loss and hyporexia. Because the disease develops slowly, there may be only mild or variable increases in liver enzymes. Increases in ALP, GGT, bilirubin, and bile acids are usual. Leukocytosis is an uncommon finding. In advanced cases ultrasonographic examination often demonstrates dramatic changes in intrahepatic and extrahepatic bile ducts, showing marked segmental dilations with areas of stenosis that may lead the operator to believe there is an obstruction. The liver has markedly hyperechoic portal areas and nodularity to the parenchyma. Liver aspirates may show increased numbers of small lymphocytes, but generally cytology is not helpful in the diagnosis. Ascites and hepatic encephalopathy occur late in the disease as a result of acquired portal hypertension and hepatic dysfunction. This syndrome is one of the few feline liver diseases in which ascites is a prominent feature.

The treatment for chronic lymphocytic cholangitis involves using antiinflammatory or immunosuppressive therapy in addition to supportive therapy as described for neutrophilic cholangitis. A European report evaluating cats with lymphocytic cholangitis treated with corticosteroids found no significant improvement in liver enzymes or biopsy, concluding that corticosteroids had no significant effect on the course of the disease (Rothuizen, 2006). This author theorized that an immune-mediated etiology was less likely. The author also reports that a second group of cats with lymphocytic cholangitis had a better response when treated with ursodeoxycholic acid. This finding is not completely unexpected because ursodeoxycholic acid has been shown to have a positive treatment effect in human patients with chronic primary biliary cirrhosis.

CHOLANGITIS ASSOCIATED WITH LIVER FLUKES

Liver fluke infestation is associated with chronic cholangitis in cats. The trematode *Platynosomum* spp. is the most common genus identified and is found in subtropical and tropical climates of the world. The life cycle of *Platynosomum* spp. includes two intermediate hosts, the first being a land snail. The second intermediate host is usually a lizard, gecko, or toad. Affected cats acquire the parasite by ingesting the second intermediate host. Immature

liver flukes then migrate from the intestine through the bile ducts to the liver. Liver fluke infections cause marked thickening and cystic dilation of the bile ducts. Severe ectasia of the bile ducts or bile duct obstruction can occur. Microscopically marked periductal and portal fibrosis with mild-to-severe chronic inflammation are characteristic. Adult flukes or operculated eggs may be observed within the bile ducts on histopathologic examination.

Affected clinical cases are generally adult outdoor cats that have contact with the second intermediate host of the liver fluke. The severity of clinical signs and liver biochemistry is usually proportional to the degree and duration of the parasitism. The clinical signs are varied and range from asymptomatic cases to hepatic failure and death. Episodes of vomiting, anorexia, and fever are common; and substantial increases in liver enzymes are observed. Icterus from severe cholestatic liver disease or bile duct obstruction can occur. Peripheral eosinophilia was reported early in the disease in experimental infections in cats.

The diagnosis is supported by ultrasonographic findings of bile duct enlargement and tortuosity. It is important to note that other causes of cholangitis can result in similar large ductular changes as well. A definitive diagnosis requires identification of operculated fluke eggs on fecal examination or the presence of eggs or flukes in bile ducts on liver biopsy. The recommended treatment is praziquantel (20 to 30 mg/kg PO q24h for 3 days).

LYMPHOCYTIC PORTAL HEPATITIS

A subset of cats has lymphocytic portal hepatitis on liver biopsy. This condition is generally associated with mild inflammatory liver disease described by small numbers of lymphocytes, with some neutrophils and plasma cells limited to the portal areas. As opposed to cats having cholangitis (inflammation centered on bile ducts), the lymphocytic portal hepatitis cases lack bile duct involvement, infiltration of inflammatory cells into hepatic parenchyma (characterized by disruption of the limiting plate), or periportal necrosis.

Lymphocytic portal hepatitis is thought to be a common histologic finding in liver biopsies of older cats. In a retrospective study 82% of cats older than 10 years had histopathologic changes consistent with lymphocytic portal hepatitis, whereas only 10% of cats younger than 10 had these histopathologic changes (Gagne et al., 1999). These observations suggest that this histologic finding is either a common aging change or possibly a subclinical form of a specific disease. The lymphocytic portal hepatitis appears to progress slowly with varying degrees of portal fibrosis and bile duct proliferation but without pseudolobule formation. Because of the presence of lymphocytes and plasma cells in portal areas and the lack of identifiable concurrent diseases, some have speculated that lymphocytic portal hepatitis may be an immune-mediated disease; but the WSAVA Liver Standardization Group considers the histologic diagnosis to be a nonspecific reactive change possibly reflecting extrahepatic disease. Liver enzymes are quite variable or normal, and icterus is uncommon. Most cats with this diagnosis have a prolonged survival, bringing speculation into the rationale for immunosuppressive therapy. There are no data on the role of immune mechanisms in the initiation and/or perpetuation of lymphocytic

portal hepatitis, and controlled studies on therapy are also lacking. The mean survival for cats with lymphocytic portal hepatitis was reported to be 3 years, but the reader should note that most all of the cases were over 10 years of age at the time of diagnosis and death from other diseases becomes more common in cats over 10 years of age.

CHAPTER 134

Portosystemic Shunts

KAREN M. TOBIAS, Knoxville, Tennessee

Portosystemic shunts (PSSs) are vascular anomalies that divert blood from the abdominal to the systemic venous circulation while bypassing the hepatic sinusoids. Products absorbed from the intestines are delivered to the heart without undergoing the extraction and detoxification processes that are normally performed by hepatocytes. This reduction in hepatic blood flow and function leads to decreases in protein production and glycogen storage, reticuloendothelial dysfunction, and altered metabolism of ammonia and other toxins. PSSs can occur as congenital anomalies or may develop secondary to liver disease and portal hypertension. Although clinical signs from multiple acquired shunts must be managed medically, congenital PSSs have been treated successfully with surgery in many dogs and cats.

ANATOMY

In dogs the ductus venosus, which carries oxygenated placental blood to the fetal systemic circulation while bypassing the hepatic circulation, normally closes within 10 days of birth. Abnormal patency of this vessel, or abnormal communications between the fetal cardinal and vitelline venous systems, results in a congenital PSS. Congenital

PSSs usually occur as single large vessels, although some animals have two or more shunts. Common types of congenital PSSs include intrahepatic portocaval shunts, such as a patent ductus venosus, and extrahepatic portocaval or portal-azygos shunts. In a small percentage of dogs with congenital PSSs, the prehepatic portal vein is absent.

ETIOLOGY

Congenital PSSs are reported in 0.18% of all dogs and 0.05% of mixed-breed dogs. Yorkshire terriers are the most commonly reported breed in the United States; risk of a congenital PSS in this breed is 59 times greater than in mixed-breed dogs and 36 times greater than in all other breeds combined. Increased risk has also been noted in a variety of other dog breeds and in Himalayan cats; thus an underlying hereditary cause is suspected. Familial relationships have been noted in Irish wolfhounds with PSS, and incidence of the disease has been reduced by breeding outside of these lines. In Yorkshire and cairn terriers, inheritance is not simple dominant, simple recessive, or sex linked. Breeding of dogs with congenital portal vein hypoplasia (hepatic microvascular dysplasia) can result in offspring with PSSs, suggesting that the diseases may be related.

SIGNALMENT, HISTORY, AND CLINICAL SIGNS

Congenital intrahepatic and extrahepatic PSSs are usually diagnosed in immature animals. No sex predilection is evident. Intrahepatic PSSs are found primarily in large-breed dogs such as Irish wolfhounds and in medium-sized breeds such as Australian shepherds and Australian cattle dogs. Extrahepatic PSSs occur primarily in small-breed dogs. In cats PSSs are most often extrahepatic.

Clinical signs associated with PSSs involve the nervous system, gastrointestinal tract, and urinary tract. General clinical signs include poor growth rate, weight loss, fever, polydipsia, and anesthetic or tranquilizer intolerance. Neurologic dysfunction is seen in most animals with PSSs and may include lethargy, ataxia, head pressing, circling, seizures, behavioral changes, and amaurotic blindness. Gastrointestinal clinical abnormalities may include anorexia, vomiting, and diarrhea. Some dogs have no apparent signs or present only with signs of cystitis or urinary tract obstruction. Many cats have hypersalivation and seizures, and some have unusual copper-colored irises.

Hepatic Encephalopathy

Hepatic encephalopathy has been recognized in animals with PSSs, end-stage liver disease, and congenital urea cycle enzyme deficiencies. Clinical signs include depression, dementia, stupor, and coma. Muscle tremors, motor abnormalities, and focal and generalized seizures have also been reported. Precipitating factors of hepatic encephalopathy include protein overload, zinc deficiency, arginine deficiency in cats, hypokalemia, alkalosis, hypovolemia, hypoxia, gastrointestinal hemorrhage, infection, azotemia, constipation, drugs, and transfusion of stored blood that is high in ammonia. Increased cerebral sensitivity to sedative, analgesic, and anesthetic agents may induce coma in animals with PSSs, even when normal dosages of the drugs are used.

DIAGNOSIS

Abnormalities found on hemograms of some animals with PSSs include leukocytosis, anemia, and microcytosis. In dogs severity of preoperative leukocytosis is correlated with postoperative outcome. Biochemical abnormalities associated with PSSs in dogs include decreases in blood urea nitrogen, protein, albumin, glucose, and cholesterol and increases in serum alanine aminotransferase and alkaline phosphatase. Increase in alkaline phosphatase is most likely from bone growth since cholestasis is not usually a problem in animals with PSSs. Albumin less than 1.3 g/dl usually indicates a poor prognosis. Cats with PSSs may have normal albumin and cholesterol concentrations but usually have increased liver enzymes. Up to half of dogs with congenital PSSs have prolonged partial thromboplastin times; however, this does not usually result in a clinically significant problem.

Urine abnormalities include low urine specific gravity and ammonium biurate crystalluria. At magnifications of 400× or more, ammonium biurate crystals often have a

spiky shape and golden color. Abnormal urine sediment suggestive of cystitis (hematuria, pyuria, and proteinuria) in animals with PSSs is most likely associated with inflammation or infection secondary to crystalluria or urolithiasis (urate).

Hepatic histologic changes in animals with PSSs include generalized congestion of central veins and sinusoids, lobular collapse, bile duct proliferation, hypoplasia of intrahepatic portal tributaries, proliferation of small vessels and lymphatics, diffuse fatty infiltration, hepatocellular atrophy, and cytoplasmic vacuolization. These pathologic changes are variable and can also be seen in dogs with congenital portal vein hypoplasia (hepatic microvascular dysplasia) that do not have single congenital shunts and in dogs with other hepatic diseases; thus liver biopsy cannot be used for definitive diagnosis of a PSS.

Liver Function Tests

Although history, physical examination, and routine laboratory tests may be suggestive of portosystemic shunting, function tests such as the ammonia tolerance test (ATT) and measurement of fasting and postprandial serum bile acid concentrations are more reliable for diagnosing liver dysfunction.

Bile Acids

During food intake neurohumoral and hormonal factors such as cholecystokinin stimulate gallbladder contraction and excretion of bile acids into the small intestines, where they form micelles that enhance lipid emulsification and absorption. At least 95% of intestinal bile acids are actively resorbed in the ileum and transported by portal blood back to the liver via the enterohepatic cycle. In healthy animals bile acid concentrations are increased minimally after a meal because of rapid first-pass hepatic extraction.

Serum bile acid concentrations increase in conditions that affect hepatocellular uptake, such as cholestasis or primary hepatic disease, or those that alter vascular flow to the liver, such as PSSs. They are not significantly affected by dehydration, hypovolemia, or passive hepatic congestion, although results can be mildly affected by lipemia and hemolysis. No special techniques are required for handling and storage of serum for bile acid samples. Prolonged fasting may result in normal bile acid concentrations in animals with PSSs; therefore fasting and 2-hour postprandial samples should be analyzed. Most protein-restricted diets, particularly those used in animals with liver disease, have sufficient fat to stimulate gallbladder contraction.

Bile acid concentrations are usually very high ($\geq 100 \mu\text{mol/L}$) in dogs with PSSs, although in one report some dogs with PSSs had serum bile acids of $25 \mu\text{mol}$ per liter or less (Winkler et al., 2003). Falsely lowered results may occur with delayed absorption from prolonged intestinal transit time, lack of gallbladder contraction because of inadequate food intake or delayed gastric emptying, or malabsorption/maldigestion with subsequent decrease in enterohepatic recirculation. Postprandial bile acid concentrations are less than fasting in 20% of animals because of spontaneous interdigestive gallbladder contraction or

with prolongation of gastric emptying or intestinal transit times. Measurement of urine bile acids is less sensitive than measurement of serum bile acids for detecting liver disease.

Bile acids may be increased falsely in some patients. Increases in postprandial bile acids that were mild ($>31\mu\text{mol/L}$) or moderate to severe ($>80\mu\text{mol/L}$) were reported in 79% and 34% of Maltese, respectively (Tisdall et al., 1995). Most of these dogs had normal ATT, and bile acids were significantly lower when measured by high-performance liquid chromatography, indicating that bile acids measured spectrophotometrically in Maltese may be increased by some other cross-reacting substance.

Ammonia

Increased resting ammonia concentration usually indicates decreased hepatic mass or shunting of portal blood. Concentrations of blood ammonia are not well correlated with severity of hepatic encephalopathy, and ammonia levels may be normal in up to 21% of dogs with PSSs, especially after prolonged fasting or with effective medical treatment. In dogs with PSSs, sensitivity of postprandial ammonia is 91% 6 hours after feeding compared to 81% before feeding. Since erythrocytes contain two to three times the amount of ammonia in plasma, improper sample cooling, hemolysis, incomplete plasma separation, or delays in sample analysis falsely increase ammonia values. Concentrations of ammonia measured with tabletop analyzers can be increased falsely if ammonia-based cleaners are used nearby or if ammonia-rich skin oils contaminate the apparatus.

The ammonia tolerance test was developed to provide a more accurate diagnosis of liver dysfunction. A heparinized baseline sample is taken after a 12-hour fast, and ammonium chloride is administered orally by stomach tube or in gelatin capsules (0.1 g/kg, maximum 3 g) or as an enema (2 ml/kg of a 5% solution inserted 20 to 35 cm into the colon). A second blood sample is obtained 30 minutes after ammonium chloride administration. Blood samples are transported on ice for immediate plasma separation and analysis. Results are invalid after oral ammonium chloride administration if vomiting occurs and after rectal administration if diarrhea or shallow rectal instillation occurs.

Diagnostic Imaging

Diagnosis of microhepatica from survey abdominal radiographs is usually based on an upright, more cranial stomach position. Renomegaly has been reported in dogs with PSSs; its etiology has not been determined. Urate calculi are normally radiolucent but occasionally are seen in the renal pelvis, ureter, or bladder on survey films. To definitively diagnose a portosystemic shunt and determine its location, imaging techniques such as angiography, ultrasonography, scintigraphy, computed tomography, and magnetic resonance angiography can be used.

Ultrasonography

Ultrasonographic evidence of PSSs includes microhepatica, decreased numbers of hepatic and portal veins, and detection of the anomalous vessel. Extrahepatic PSSs

can be more difficult to diagnose with ultrasonography because the patient is usually small and structures such as ribs and intestines can obscure the vessel. Color flow Doppler imaging is useful for detecting changes in direction and rate of blood flow in the portal vein. The combination of small liver, large kidneys, and uroliths is highly suggestive of shunting in dogs, and dogs and cats with extrahepatic shunts have reduced portal vein to aorta ratios.

Nuclear Scintigraphy

In dogs technetium $^{99\text{m}}\text{Tc}$ is extracted from the circulation primarily by the liver. In animals with PSSs $^{99\text{m}}\text{Tc}$ rapidly circulates to the heart and lungs. Normal dogs have a shunt fraction of less than 15% on scintigraphy; most dogs with shunts have fractions greater than 60%. Rectal scintigraphy primarily provides a diagnosis of shunting or no shunting and may be inaccurate with shallow or incomplete instillation or in dogs with colonic fecal contents. Percutaneous splenic injection of $^{99\text{m}}\text{Tc}$ permits a reduction of up to 90% in the dosage of the radioactive material, reducing exposure of personnel. In addition, clearance is more rapid with this technique, so that animals are releasable within an hour of study completion. The technique may also provide more information regarding number (single versus multiple) and termination (portocaval versus portoazygos) of the PSSs; composite images frequently produce a portogram that guides the surgeon in shunt location. Nondiagnostic scans may occur in dogs with thin spleens if the $^{99\text{m}}\text{Tc}$ is accidentally injected outside of the splenic parenchyma.

Portography

Presence, number, and location of PSSs can be determined with intraoperative mesenteric portography (IOMP). Celiotomy is usually required unless the clinician has experience with transvenous retrograde portography. During IOMP water-soluble contrast medium (maximum total dose 2 ml/kg) is injected into a catheterized jejunal or splenic vein, and one or more radiographs are taken during completion of the injection. Alternatively the spleen can be injected directly and percutaneously in a sedated dog. However, there is a risk of splenic laceration with this technique, and images are often of poorer quality compared to direct intravascular injection. Catheterization of the abdominal arterial and venous systems can also provide diagnostic angiograms during the venous return phase of an arteriogram or consequent to selective venous injections of vessels drained by the shunt. Retrograde placement of two angiographic catheters via the jugular vein can permit simultaneous injections of contrast into the caudal vena cava and the distal portal vein (which is entered via the shunt). This delineation is typically performed during percutaneous stent and coil closure of an intrahepatic shunt (see below).

Differentiation of intrahepatic and extrahepatic PSSs may be made on most portograms. If the most caudal loop of the shunt or the point at which the shunt diverges from the portal vein is cranial to the T13 vertebra, the shunt location is probably intrahepatic. Shunt location varies by one half to three fourths of a vertebral length, depending on the phase of respiration.

DIFFERENTIAL DIAGNOSES

Single congenital portosystemic shunts must be differentiated from neurologic conditions such as hydrocephalus and epilepsy and from other primary hepatic diseases, including congenital portal vein hypoplasia (hepatic microvascular dysplasia) and multiple acquired shunts secondary to portal hypertension. Congenital portal vein hypoplasia is found in many small breeds predisposed to congenital PSSs and can cause similar biochemical, hematologic, histologic, and clinical changes, although gross shunting is not detectable by portography or scintigraphy. Protein C activity (100% being normal) may be helpful in differentiating congenital vascular diseases; protein C activity $\geq 70\%$ in dogs with portal vein hypoplasia and $< 70\%$ in dogs with PSS (Olivier et al., 2006).

MEDICAL MANAGEMENT OF PSS

Medical management of animals with PSSs includes correction of fluid, electrolyte, and glucose imbalances and prevention of hepatic encephalopathy by controlling precipitating factors. Dietary protein is restricted to reduce substrates for ammonia formation by colonic bacteria. Daily energy intake should be calculated based on ideal body weight, since patients with shunts may be thin or have poor muscle development. At least 30% to 50% of dietary calories should be provided as easily digested, complex soluble carbohydrates; and diets for dogs and cats should contain 15% to 30% and 20% to 40% of fat, respectively, on a dry matter (DM) basis. Protein requirements are approximately 2.11 g of crude protein per kilogram of body weight per day or approximately 15% to 20% DM and 30% to 35% DM for dogs and cats, respectively. Soybean meal and dairy proteins are often recommended because of their high digestibility and levels of soluble carbohydrates and fermentable fibers. If home-made diets are used, zinc, fat-soluble vitamins, and vitamins B and C should be supplemented.

Lactulose can be used to decrease intestinal transit time, acidify colonic contents, and reduce production and absorption of ammonia. Lactulose may be given orally or by enema; dosages should be regulated so that feces is soft but formed. Yogurt with active cultures can be substituted in place of lactulose to alter colonic flora.

Gastrointestinal hemorrhage (Chapter 114), intestinal parasites, and cystitis should be treated appropriately. Gastric ulcers may be observed even following partial successful closure of a shunt and may require long term management with proton-pump blockers. Urate uroliths may respond to low-protein diets; renal calculi reportedly have dissolved after shunt ligation. In severely encephalopathic animals oral antibiotics effective against urease-producing bacteria such as neomycin or metronidazole can be administered to decrease bacterial populations; however, clinicians should be aware of the potential toxicity of these drugs. Enemas with water and lactulose may be used to reduce colonic bacteria and substrates; intravenous fluids should be administered to obtunded animals. Fresh frozen plasma or hetastarch may be required in patients with coagulopathy or decreased oncotic pressure, respectively. Cats may require phenobarbital or other anticonvulsive medications to prevent and control seizures. For patients with severe neurologic signs,

a neurologist should be consulted about optimal antiseizure therapy prior to an interventional procedure.

Prognosis With Medical Management

With proper medical management, weight and quality of life stabilizes or improves with treatment in most animals. One third of dogs do well with medical management as the sole method of treatment, with many living to 7 years of age or older (Watson and Herrtage, 1998). Duration of survival with medical management alone has been correlated to age at initial signs and with blood urea nitrogen (BUN) concentration; dogs that are older at presentation or have a higher BUN live longer. Over half of dogs treated with medical management alone are euthanized, usually within 10 months of diagnosis, because of uncontrollable neurologic signs and in some cases progressive hepatic fibrosis and subsequent portal hypertension. In some older dogs with PSSs onset of clinical signs may be associated with other hepatic diseases, and the shunt may be an incidental finding. With medical management alone, survival time of cats with PSSs, particularly those that are neurologic, is usually less than 2 years.

SURGERY

Surgical treatment is recommended in most patients to improve long-term outcome. Options include acute ligation with suture; gradual occlusion with ameroid constrictors, cellophane banding, or hydraulic occluders; or embolization with coils. Prognosis for successful surgical treatment is best for dogs with extrahepatic shunts, for animals that undergo complete shunt occlusion, and for those that present with urinary tract signs and no hepatic encephalopathy. When suture ligation is performed, portal and central venous pressures are measured to determine the acceptable degree of attenuation since 30% to 60% of animals cannot tolerate complete acute occlusion. Compared to gradual attenuation, acute complete or partial ligation of a PSS with suture is associated with higher complication rates, including perioperative death in 14% to 22%, seizures in 7% to 11%, recurrence of clinical signs in 40%, and development of multiple PSSs.

Ameroid constrictors (Research Instruments N.W., Inc.) provide gradual, complete shunt occlusion over 2 to 3 weeks through device swelling and local inflammatory tissue reaction. Excellent outcomes are seen in 80% to 85% of dogs after ameroid constrictor placement, although persistent shunting may occur in 17% to 21%. Cellophane bands also cause gradual shunt occlusion secondary to fibrosis. Cellophane is obtained from candy and flower shops and is cut into strips and sterilized for use. Outcome after cellophane banding in dogs is similar to that after ameroid constrictor placement.

More recently a less invasive interventional radiology technique has been used for partial occlusion of intrahepatic PSSs. This approach involves placement of a self-expanding vascular stent within the segment of vena cava communicating with the shunt. A small catheter is advanced through the interstices of the stent into the shunt vessel. Thrombogenic coils are then delivered into the shunt and are contained by the stent (which prevents the coils from entering the caudal vena caval flow). The resultant clot-

ting partially occludes the shunt vessel at the entry into the vena cava. If the shunt is later found to be insufficiently closed, additional coils can be added relatively easily using a percutaneous, minimally invasive approach. Clinical experience at a number of referral centers suggests this can be a safe and seemingly effective treatment. However, as yet there are no reports comparing outcomes of this procedure with the surgical methods described above.

With any surgical technique, postoperative complications, particularly blindness and seizures, are more common in cats. Shunts in cats may not close after cellophane banding or silk suture ligation because of inadequate fibrous tissue response. Glucocorticoids or use of narrow constricting bands may also reduce fibrous tissue formation and result in persistence of shunting in dogs and cats.

POSTOPERATIVE CARE

After surgery animals are monitored closely for hypothermia; hypoglycemia; seizures; and signs of portal

hypertension, including shock, pain, and abdominal distention. Most animals need analgesics such as opioids. Sedation with a low dose (0.01 to 0.02 mg/kg IM) of acepromazine may be necessary if dogs are vocalizing or abdominal pressing since these activities increase portal pressure and hyperexcitability. Acepromazine does not appear to lower seizure threshold in PSS patients, but the effects may be prolonged so careful dosing is critical. About 25% of dogs develop hypoglycemia despite concurrent intravenous treatment with dextrose-containing fluids. Patients with nonresponsive hypoglycemia, poor anesthetic recovery, or signs of circulatory disturbances (decreased systolic pressure, increased capillary refill time, poor peripheral pulses, pale mucous membranes) may require treatment with one or more doses of steroids (0.02 to 0.1 mg/kg dexamethasone sodium phosphate IV).

As many as 18% of dogs may develop seizures after shunt ligation. Etiology is unknown; and affected animals usually do not respond to fluids, dextrose, lactulose, or enemas. Single seizures are treated with a bolus of diazepam, correction of any hypoglycemia, and administration of

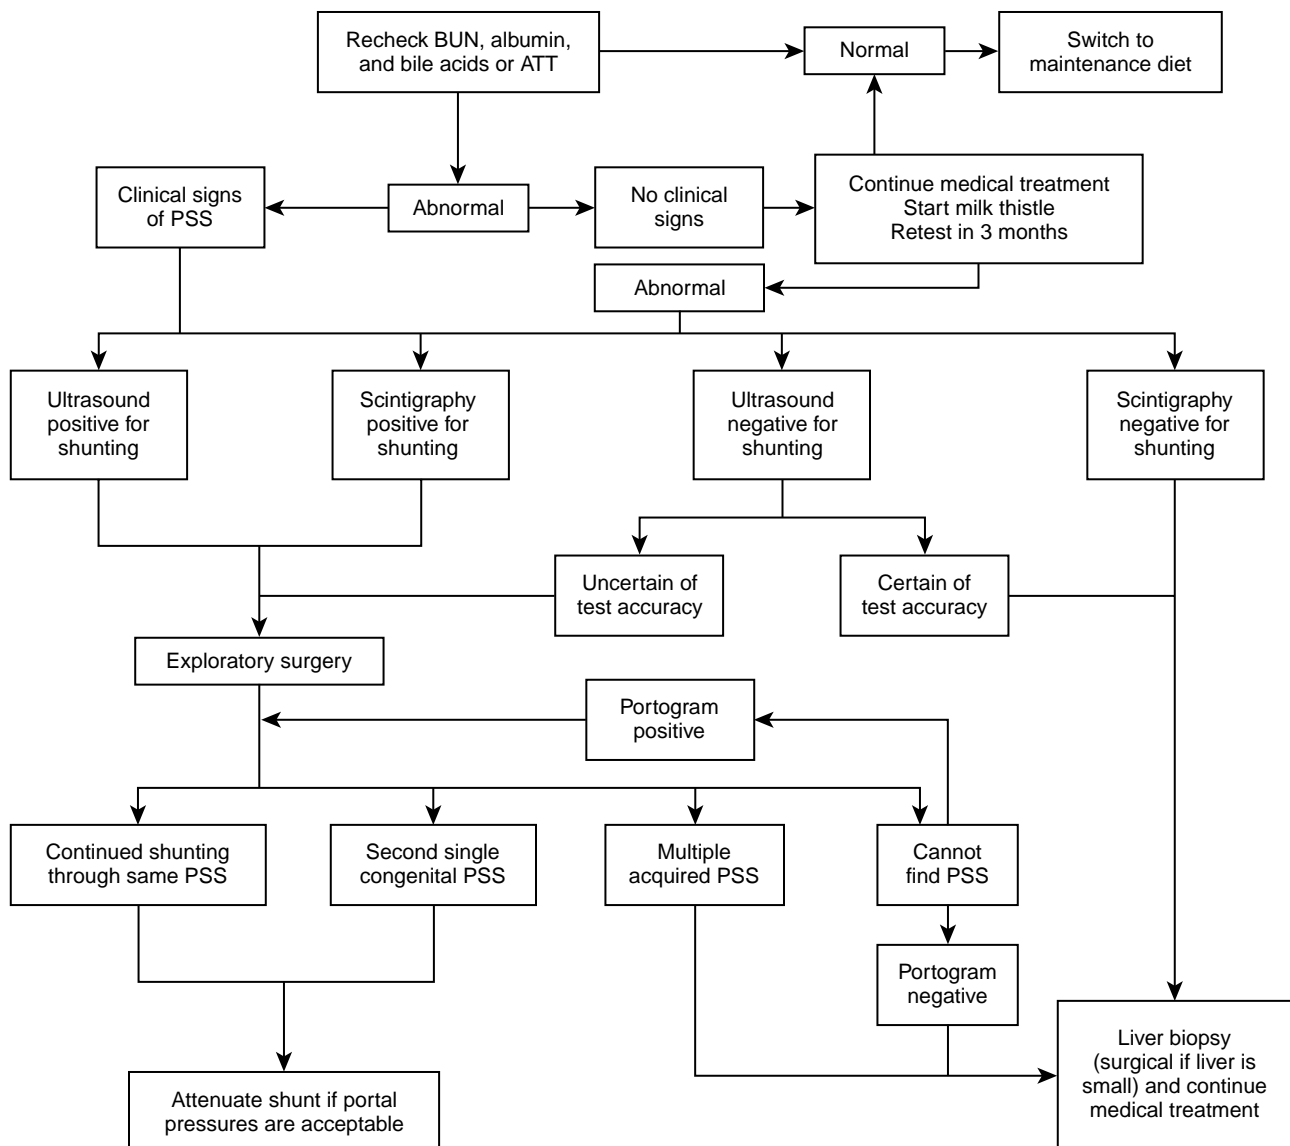

Fig. 134-1 Algorithm for evaluation of animals with single congenital shunts 3 months after surgery.

lactulose retention enemas in case there is an underlying encephalopathy. If seizures recur, animals can be treated with intravenous phenobarbital, a continuous rate infusion of diazepam in 0.9% saline or 3% sodium bromide in sterile water (dogs only), and later placed on a maintenance dose of oral phenobarbital (cats) or potassium bromide (dogs). Animals with uncontrollable seizures are treated with a continuous intravenous infusion of propofol (0.025 to 1 mg/kg/minute) over 12 to 24 hours and intravenous mannitol every 6 hours. Prognosis is poor for animals with postoperative seizures, and many that survive continue to have neurologic problems. At our clinic postoperative seizures are rare in dogs; most dogs receive intraoperative hetastarch for oncotic support, preoperative and postoperative acepromazine for tranquilization, and postoperative dexamethasone as needed for signs of functional hypocortisolemia. Surgery time is decreased by use of ameroid constrictor placement without jugular catheter placement or portal venous pressure measurements. It is unknown which of these factors plays the greatest role in reducing postoperative seizure rates in dogs.

Portal hypertension occurs most frequently after acute ligation. Treatment includes intravenous fluids, hetastarch, broad-spectrum systemic antibiotics, fresh frozen plasma and low-molecular weight heparin if coagulation times are prolonged, and usually surgery to remove the constrictor or ligature. Factors that may increase portal pressure after surgery include excessive intraoperative fluid administration, increased systemic blood pressure from anesthetic recovery, and increased intraabdominal pressure from bandages, pain, or vocalization. Portal hypertension occasionally resolves with intensive medical management without surgery.

Medical management is continued after surgery until liver function improves. Frequently animals can be gradually weaned off of lactulose 2 to 6 weeks after the surgery unless they are constipated or clinical signs recur. Bile acids and albumin are evaluated 3, 6, and 12 months after the surgery to assess liver function. Protein in the diet can be increased gradually once bile acids are nor-

mal. In dogs with mildly increased bile acids and normal albumin, it may be necessary to monitor clinical response to diet change to determine whether protein content can be gradually increased. Milk thistle may be used in animals with persistently increased bile acids or ammonia concentrations to improve hepatic function and regeneration. Animals with persistent clinicopathologic abnormalities may require further workup to determine the underlying cause (Figure 134-1). Yorkshire terriers commonly have increased bile acids 3 to 6 months after surgery despite clinical improvement; this may be secondary to underlying congenital portal vein hypoplasia.

Canine Biliary Mucocele

HEIDI A. HOTTINGER, *Houston, Texas*

Biliary mucoceles were rarely reported in dogs before 1990 but have since become one of the most common causes of extrahepatic biliary disease in canine patients. Their distinct characteristics—grossly, histologically, and ultrasonographically—make it unlikely that mucoceles were previously misdiagnosed or missed altogether. Therefore it seems that this is a newly developing disease process in veterinary medicine for which an etiologic cause has not yet been determined.

PATHOGENESIS

A biliary mucocele is an accumulation of the mucus component of bile within the gallbladder. Grossly it appears as shiny green-black gelatinous material that has lamellar striations along fracture lines (Fig. 135-1). Functional or structural obstruction of the cystic or common bile duct is the usual cause in humans and has been proposed as a cause in the dog. Obstruction can lead to resorption of the liquid portion of bile, allowing the mucinous component to accumulate within the gallbladder. However, studies to date do not support this theory. Primary obstruction of the cystic or common bile ducts is rarely found on diagnostic tests or at the time of surgery, and histologically there is typically evidence of hyperplasia of the mucus-secreting glands of the gallbladder mucosa. An inflammatory or bacterial component is rarely present in reported cases. Therefore primary disease of the mucus-secreting glands of the gallbladder is the more likely cause of biliary mucoceles in dogs. Associated diseases such as underlying

liver disease, chronic pancreatitis, and Cushing's disease have been suggested as predisposing factors for biliary mucoceles; but none have been proven to have a definitive cause-and-effect association. Even though these conditions have not been proven to be predisposing causes, no other predisposing factors have been identified; thus all patients should be evaluated carefully for other underlying diseases that may be predisposing or contributing conditions. The recent recognition of biliary mucoceles in veterinary medicine may also suggest a role for nutritional or environmental factors in the etiology. Genetics may also be relevant, as evidenced by the overrepresentation of a few breeds, in particular Shetland sheepdogs, cocker spaniels, dachshunds, and miniature schnauzers.

DIAGNOSTICS

As with any disease or disease process, the diagnosis of a biliary mucocele is achieved by assimilating data from the presentation and owner history, physical examination, laboratory data, imaging studies, and histopathology.

Patients typically present as middle-aged to older, small-to-medium breed dogs. Although no breed predispositions have been reported definitively, Shetland sheepdogs appear to be overrepresented, as do dachshunds, miniature Schnauzers, and cocker spaniels (Aguirre AL, et al, 2007). No sex predilection is evident.

Most dogs with clinical evidence of gallbladder mucoceles present to the veterinarian with a history of subacute-to-acute onset of nonspecific clinical signs. Signs of systemic illness typically include vomiting, inappetence or anorexia, lethargy, diarrhea, polydipsia and polyuria, and vague signs of discomfort. Any combination of these symptoms may be present, or the mucocele may be found as an incidental finding with no clinical symptoms of systemic disease. Physical examination findings are also vague in nature and may include abdominal pain, icterus, tachypnea, tachycardia, dehydration, pendulous abdomen or fluid wave, and fever. Patients may also present with no abnormal examination findings. Because historical and physical examination findings are vague and general, many animals are presumed to be suffering from other disease processes such as pancreatitis, necessitating careful examination and review of all available information to achieve an accurate and timely diagnosis.

The most common laboratory abnormalities include increases in serum liver enzyme activity (alkaline phosphatase, alanine aminotransferase, aspartate aminotransferase, γ -glutamyltransferase, increased total bilirubin) and elevated white blood cell counts. Abdominal radiographs have limited usefulness in the diagnosis of a biliary

Fig. 135-1 A biliary mucocele with green-black gelatinous mucus material and lamellar striations along fracture lines.

Fig. 135-2 Ultrasound view of a gallbladder mucocoele demonstrating the characteristic striated or stellate (kiwi-shaped) pattern within the lumen of the gallbladder.

mucocoele but may be critical in ruling out other causes of the historical or physical findings such as gastrointestinal obstruction, abdominal mass, or other causes of vomiting and lethargy. Although uncommon, choleliths may be visible on abdominal radiographs, and these occasionally may lead to biliary tract obstruction. Abdominal ultrasound is the diagnostic test of choice for gallbladder mucocoeles, which have distinct characteristics on ultrasonographic images. The content of the gallbladder mucocoele is echogenic and nongravity dependent when ballottement or repositioning of the patient is performed, and a striated or stellate (kiwi-shaped) pattern is noted within the lumen of the gallbladder. This kiwi appearance is very specific for biliary mucocoeles (Fig. 135-2). Ultrasonography may also detect varying degrees of extrahepatic biliary obstruction caused by extension of the mucinous bile into the cystic, common, and hepatic ducts. Although the ultrasound examination can be very sensitive for the diagnosis of biliary mucocoeles, it does not always correspond as favorably to the severity of disease assessed at surgery, in particular the presence of pressure necrosis of the gallbladder wall or cystic duct that can lead to eventual rupture.

TREATMENT

Medical and surgical treatments have been reported for the management of gallbladder mucocoeles. Medical management typically involves the use of antibiotics, hepatosupportive supplements, and choleretics. It is not surprising that reports of medical management have shown limited success or failure since the mucocoele content is typically a semisolid mass of mucoid material by the time of diagnosis, which is unlikely to dissolve and pass from the gallbladder. Hydrophobic bile salts have been demonstrated to be hepatotoxins, and increased exposure of the canine gallbladder epithelium to bile salts has produced documented increases in mucus secretion. These facts suggest that future research in the field of bile acids may reveal medical interventions that will be helpful in the prevention of biliary mucocoeles and potentially even in the treatment of early mucocoeles.

Surgical management with a cholecystectomy appears to be the preferred treatment for biliary mucocoeles. This recommendation is based on the facts that histology consistently suggests that the gallbladder is the primary diseased component; the mucocoele is usually semisolid to solid at the time of diagnosis and unlikely to dissolve; the expanding size of the mucocoele typically leads to pressure necrosis of the gallbladder wall with a high risk of eventual rupture and development of bile peritonitis; and the risk that the mucocoele can develop a secondary bacterial infection that results in a high mortality rate when associated with bile peritonitis.

At the time of surgery it is common to find localized peritonitis in the cranial abdomen, which presents as adhesions of the omentum, stomach, liver and diaphragm to the necrotic gallbladder wall. This localized peritonitis helps to contain rupture of the gallbladder or cystic duct, but occasionally rupture progresses to generalized bile peritonitis. The majority of reported mucocoeles are sterile; thus the prognosis with rupture of the gallbladder wall is much more favorable than that associated with septic bile peritonitis. If adhesions are present, they should be gently broken down, and the gallbladder dissected from the hepatic fossa. Before removal of the gallbladder, the common and hepatic bile ducts should be carefully evaluated for patency. Digital manipulation can be used to express the common bile duct in many patients by gently manipulating the contents normograde into the duodenum. If mucocoele contents are present in the common bile duct, digital expression may not be possible. Normograde and retrograde lavage is necessary in this scenario to establish patency. Normograde lavage is accomplished through a cholecystotomy incision and passage of a flexible catheter into the cystic duct. It is not usually possible to pass the catheter past the cystic duct because of the presence of a sharp bend and a valve at the junction of the cystic and common ducts. Retrograde lavage is achieved through an antimesenteric duodenotomy over the major duodenal papilla, allowing passage of a flexible catheter through the sphincter of Oddi. Once patency of the hepatic and common bile duct is verified, the gallbladder can be removed. Necrosis and/or rupture of the biliary tree in patients with mucocoeles typically occur at the apex of the gallbladder but can also occur in the cystic duct. Care should be exercised to ensure that the site of ligation is distal to all necrotic tissue and sites of rupture that may be present in the cystic duct. If necrosis of the common bile duct is present, reconstruction techniques typically are unsuccessful, and the prognosis is grave. There is a very low incidence of infection associated with mucocoeles, but it is still recommended to obtain culture samples at the time of surgery. Samples should be collected from bile, the gallbladder wall, and the liver. Biopsy samples of the liver and gallbladder should also be submitted.

Copious abdominal lavage is indicated if bile rupture is present or if spillage of bile occurred during surgery. Use of a closed suction drainage system is necessary only when generalized peritonitis is present.

PROGNOSIS

Long-term prognosis is very good for patients treated with cholecystectomy that survive the perioperative period.

Unfortunately perioperative mortality can be high (20% to 25%), and no predictors for survival have been identified. Reported preoperative serum biochemistry values and ultrasonographic findings have been similar in survival and nonsurvival groups. Likewise the presence of biliary tract rupture and bile peritonitis or the development of postoperative pancreatitis had no impact on survival. The immediate postoperative period is the most critical time for these patients. The reported causes of perioperative mortality include cardiopulmonary arrest, supposed thromboembolic disease, septic bile peritonitis, and pancreatitis. Preoperative and postoperative pancreatitis is a reported complication that seems to have a high enough incidence rate to warrant some simple preventive measures. Withholding food for 24 to 48 hours after surgery, keeping rich aromas away from the cage, and monitoring pain and comfort levels closely have the potential to improve the perioperative recovery period significantly. Many patients with biliary mucoceles also have abnormalities on liver biopsy with the typical histologic changes, including variable degrees of bile duct hyperplasia, portal fibrosis, bile stasis, cholangiohepatitis, nodular regeneration, and hepatocellular vacuolar change. Despite these changes, elevations in liver enzymes return to normal in many patients after surgery. Concurrent underlying liver disease does remain in some patients, which may require medical management for optimal long-term results.

The excellent long-term outcome of patients with biliary mucoceles treated with cholecystectomy indicates that the gallbladder is the primary diseased organ. Early intervention before the development of bile peritonitis is preferable in terms of patient morbidity but does not

seem to have a detrimental effect on survival in reported studies. It is my opinion that perioperative mortality will continue to improve as this disease process is recognized in earlier stages and patients receive surgical treatment before debilitation of the hepatobiliary system. This can be a difficult recommendation to make for a nonsymptomatic dog in light of the reported perioperative mortality rate. However, only a few clinical reports exist in the literature, and they compile data from dogs in the early phases of recognition and treatment of this disease. Subsequent reports may find a higher success rate as this disease is diagnosed and managed earlier and more aggressively.

CHAPTER 136

Esophageal Feeding Tubes

HOWARD B. SEIM, III, *Fort Collins, Colorado*

Feeding the inappetent patient has been shown to decrease both mortality and morbidity. Further, if the gastrointestinal tract is functional, feeding by the enteral route is preferred to a parenteral route. Enteral tube feeding is a more physiologic means of nutrition. It is easier and less expensive and has fewer complications than parenteral feeding. As a general rule, the closer feeding tubes are placed to the mouth, the more efficient the assimilation and digestion of nutrients and the greater the flexibility in formula composition. Conversely the further tube placement is from the mouth, the less efficient is the

assimilation and digestion of nutrients, and greater care must be taken in choosing the type and composition of the diet. In addition, the location of gastrointestinal tube feeding dictates diameter of the feeding tube, and tube diameter in turn dictates usable feeding formulas based on viscosity and particulate matter size. The most common tube feeding routes of administration for enteral alimentation include oral, nasoesophageal, pharyngostomy, esophagostomy, gastrostomy, gastroduodenostomy, and jejunostomy. Each route has specific indications, contraindications, advantages, disadvantages, and complications.

This chapter focuses on the use of esophagostomy feeding tubes (E tubes) in dogs and cats. E tubes are easy to place, well accepted by the patient, and have few complications.

INDICATIONS

Nutritional support is indicated in patients unable to meet nutritional demands because of an inability or reluctance to consume a prescribed diet. E tube feeding is indicated in anorexic patients of any cause having a functional gastrointestinal tract distal to the site of tube placement. E tube feeding is particularly useful in anorexic cats with hepatic lipidosis, anorexic cancer patients, or patients having disorders of the oral cavity or pharynx. Surgical procedures that lend themselves to E tube placement include mandibulectomy, maxillectomy, or cleft palate repair.

CONTRAINDICATIONS

E tube placement is contraindicated in patients with esophageal dysfunction such as megaesophagus, esophagitis or esophageal stricture, gastrointestinal dysfunction or obstruction, and persistent vomiting or patients that are a poor anesthetic risk.

TECHNIQUE

Tube Placement

Patients require general anesthesia and endotracheal intubation for E tube placement. They are placed in right lateral recumbency with left side uppermost. Although the tube can be placed on either the right or left side of the midcervical region, the esophagus lies slightly left of midline, making left-sided placement more desirable. The tube entry site in the left lateral midcervical area is aseptically prepared. The head and neck are slightly extended, and the mouth is held open using a mouth speculum. Esophageal feeding tubes are generally polyvinyl chloride or Silastic in composition. In dogs a 20- to 24-Fr-diameter tube is used; in cats a 14- to 18-Fr tube is used. Before tube

placement it is suggested to enlarge the two lateral exit openings of the feeding tube or cut off the distal rounded end of the feeding tube to encourage smoother flow of blended diets through the tube (Fig. 136-1). The feeding tube is then measured from the level of the midcervical region entry point to the level of the seventh or eighth intercostal space; this point is marked on the tube for later reference during tube placement. This ensures that the tube extends only to the mid-distal esophagus and does not cross the lower esophageal sphincter (LES). Feeding tubes that cross the LES frequently cause LES incompetence and subsequent gastroesophageal reflux. Several techniques have been described to place E tubes: one method involves using an Eld percutaneous gastrostomy feeding tube placement device (Eld device) (Fig. 136-2); another method involves the use of curved Carmalt forceps; and a third method involves the use of a specialized esophageal feeding tube applicator (esophageal feeding tube applicator, Firma Fixomed). I have not used the third method and thus will not describe it in detail.

Eld Device Technique

An Eld device originally designed for gastric tube placement can be used to place an E tube (Fig. 136-3). This technique

Fig. 136-1 Modifications of the distal orifice of the feeding tube with scissors. The orifice is elongated 3 to 4 cm without compromising the strength of the tube. (From Devitt CM, Seim HB III: Clinical evaluation of tube esophagostomy in small animals, *J Am Anim Hosp Assoc* 33:55, 1997, with permission.)

Fig. 136-2 ELD percutaneous feeding tube applicator and stylet. *Upper insert*, Close-up view to the distal tip of the applicator with the blade retracted. *Lower insert*, Close-up view of the distal end of the applicator with the blade extended. Note the eyelet for securing suture material to the blade.

Fig. 136-3 Insertion of the Eld percutaneous feeding tube applicator to the midcervical esophagus. **A**, The distal tip is palpated, and an incision is made through the skin and subcutaneous tissue over the tip of the Eld. The trocar is advanced through the esophageal wall and directed through the incision. **B**, The remainder of the shaft is advanced through the esophageal wall. **C**, The distal end of the feeding tube is secured to the eyelet of the trocar with suture material. (From Devitt CM, Seim HB III: Clinical evaluation of tube esophagostomy in small animals, *J Am Anim Hosp Assoc* 33:55, 1997, with permission.)

works best in medium- to large-sized dogs. The oblique tip of the instrument shaft is placed through the oral cavity and into the esophagus to the level of the midcervical region (i.e., equal distance between the angle of the mandible and point of the shoulder), and the tip is palpated as it creates a bulge in the cervical skin. A small skin incision is made over the device tip. The spring-loaded instrument blade is activated until it penetrates the esophageal wall, cervical musculature, and subcutaneous tissue and is visible through the skin incision. The incision is carefully enlarged in the subcutaneous tissue, cervical musculature, and esophageal wall with the tip of a No. 15 scalpel blade to allow penetration of the instrument shaft through the tissues. A 2-0 nylon suture is placed through the previously enlarged side holes of the feeding tube and through the hole in the instrument blade. The suture is tightened until the tip of the instrument blade and the feeding tube tip are in close apposition. The instrument blade is retracted into the instrument shaft so the feeding tube tip just enters the instrument shaft (i.e., deactivating the instrument blade). Sterile water-soluble lubricant is placed on the tube and instrument shaft. The instrument is retracted, and the feeding tube is pulled into the oral cavity to its predetermined measurement. The 2-0 nylon suture is removed to free the feeding tube from the instrument. See Redirection of Tube for placement into the esophagus.

Curved Forceps Technique

Placement of an E tube using curved forceps is done in a manner similar to placement using the Eld device. The animal is positioned in right lateral recumbency. With the head and neck extended, the curved end of the forceps

Fig. 136-4 **A**, For cats and small dogs the curved end of a Carmalt hemostat is passed through the oral cavity into the midcervical esophagus. **B**, The curved tip of the hemostat is then pushed up so the tip can be seen elevating the esophagus, subcutaneous tissues, and skin. The tip of the hemostat is palpated, and a skin incision is made until the tip of the hemostat is exteriorized. **C**, The distal end of the feeding tube is then grasped with the hemostat, and the hemostat is retracted, thus pulling the feeding tube into the oral cavity.

is passed through the oral cavity into the midcervical esophagus (Fig. 136-4). The curved tip of the forceps is then pushed up so the forceps tip is seen elevating the esophagus, subcutaneous tissues, and skin over the tip.

The ends of the forceps are palpated, and an incision is made through the skin down to the forceps tip so the forceps tip is exteriorized. The distal end of the feeding tube is then grasped with the forceps, and the forceps are retracted, thus pulling the feeding tube into the oral cavity.

Redirection of Tube

With either the Eld device or curved forceps method, the distal end of the tube exits the oral cavity, and the flared end of the feeding tube approaches the tube entry point. The next step is to redirect the distal end of the feeding tube back into the esophagus so that it terminates in the midthoracic esophagus. There are two methods to accomplish this: one involves using a hemostat to advance the distal tip of the catheter into the esophagus, and the second involves inserting a stylet through the side opening of the feeding tube and against its tip (Fig. 136-5).

Use of a stylet to redirect the feeding tube. In the dog a stylet (such as a rigid wire or stiff male urinary catheter) is placed through one of the side holes of the feeding tube and against the feeding tube tip. The feeding tube is lubricated and advanced into the esophagus until the entire oral portion of the tube disappears. The stylet is gently retracted from the oral cavity, taking care to ensure its release from the feeding tube. The tube must be placed to its premeasured mark. It is advised to take a radiograph to document tube location. *This technique is recommended*

Fig. 136-5 **A**, The Eld and attached feeding tube are retracted into the esophagus and exteriorized out the oral cavity. **B**, The feeding tube is redirected into the esophagus by inserting a wire stylet (dogs only) into the enlarged orifice and resting against the distal tip of the feeding tube. **C**, The tube is directed into the midthoracic esophagus and retracted or advanced to the previously marked level on the tube. (From Devitt CM, Seim HB III: Clinical evaluation of tube esophagostomy in small animals, *J Am Anim Hosp Assoc* 33:55, 1997, with permission.)

Fig. 136-6 The feeding tube is simply advanced into the esophagus using fingers (cat) or hemostats (dog).

for large- and medium- sized dogs. A metal stylet should never be used to redirect the feeding tube in a cat.

Use of forceps to redirect the feeding tube. In cats and small dogs the tube is advanced into the esophagus with fingers or hemostats until as much of the oral portion of the tube as possible is in the esophagus. It is advised to take a radiograph to document tube location (Fig. 136-6).

Esophageal Tube Applicator Technique

This technique described by von Werthern and Wess (2001) uses a specialized tube applicator. Essentially this is a large tube with a "shoe horn" bulb in the distal third of the tube. A groove 8mm wide extends from the bulb to the distal end of the tube. With the bulb portion in the midcervical esophagus, one can cut through skin, subcutaneous tissues, and esophagus into the groove of the tube. A feeding tube is then placed into the esophagus and into the tube. Because of the shoe horn shape of the applicator tube, the feeding tube can be directly aborally, avoiding the need to bring the tube through the mouth and then to redirect it aborally.

Tube Management

The tube is secured to the cervical skin with a "Chinese finger-trap" friction suture using 0 or 1-0 monofilament nonabsorbable suture material (Fig. 136-7). The exit point of the tube can be left exposed or loosely bandaged. A column of water is placed in the tube after each feeding, and the end capped. A 20-gauge hypodermic needle cap or 3-ml syringe barrel works well for this purpose, thus preventing intake of air, reflux of esophageal contents, and occlusion of the tube by diet. Most patients tolerate the tube without the need of an Elizabethan collar. E tubes can be removed immediately

Fig. 136-7 The tube is secured to the cervical skin using a "Chinese finger-trap" friction suture with 0 or 1-0 monofilament nonabsorbable suture material.

after placement or left in place for weeks to months. The tube exit site should be cleaned periodically with an antiseptic solution.

Feeding can commence immediately through the feeding tube unless otherwise contraindicated. Diets available for use include a variety of blenderized canned diets, monomeric diets, and polymeric diets. The tube entrance site should be maintained with daily inspection and cleaning with antiseptic solution. When nutritional support is no longer necessary, the tube is removed by cutting the retaining suture and pulling the tube. No further exit wound care is necessary; the hole seals in 1 to 2 days and heals in 3 to 5 days.

ADVANTAGES

The technique of midcervical E tube placement is economical and simple to perform and provides a large-diameter feeding tube. E tube placement is suitable in nutritionally compromised small animals with a functional esophagus and gastrointestinal tract. E tubes should be placed from the midcervical esophagus to the midthoracic-to-distal esophagus but should not cross the LES. Feeding via E tube can commence immediately following tube placement. Long-term use of E tubes in dogs and cats is not associated with significant complications. Following tube removal, the esophagocutaneous fistula heals readily by second intention.

COMPLICATIONS

Complications associated with E tube placement include early removal by the patient, vomiting the tube, and tube removal or migration. Minor complications include scratching at the E tube entry site, local skin infection, and mechanical problems. The most frequent owner problems include feeding difficulty or clogging of the tube with food. Tube clogging can usually be avoided if the tube is flushed with water and capped after each feeding. I have observed two cases of esophageal perforation in cats having E tube placement. These perforations were believed to occur during tube redirection with a metal stylet. Esophageal perforation has not been observed by me in cats since eliminating the stylet from placement protocol. Esophageal perforation has not been reported in the dog. No significant long-term complications have been reported; but potential complications could include esophagi-

tis, esophageal stricture, esophageal diverticulum, or subcutaneous cervical cellulitis. Reflux esophagitis can occur from improper tube placement (i.e., through the LES) or esophageal irritation from the tube itself. Midesophageal placement of silicone rubber tubes greatly reduces the incidence of esophageal injury and eliminates reflux esophagitis.

CONCLUSION

Various methods are available for providing nutritional support in small animals, including nasogastric, nasoesophageal, pharyngostomy, gastrostomy, and jejunostomy tubes. Each method has advantages and disadvantages. Although general anesthesia is required for placement, the E tube has the advantage over the nasoesophageal or nasogastric tube because it provides a large-diameter feeding tube that eliminates the need for specialized diets. E tube placement has the advantage over nasogastric, nasoesophageal, and pharyngostomy tubes because it is placed further caudad, eliminating the risk of aspiration or upper airway obstruction. E tube placement has the advantage over gastrostomy and jejunostomy tubes because it eliminates the risk of peritonitis if the gastrostomy or jejunostomy tube is prematurely dislodged, and it has the advantage over a jejunostomy tube in that E tube placement does not require laparotomy or endoscopy for placement, specialized liquid diets, or expensive equipment for diet delivery.

Oxygen Therapy

DENNIS T. CROWE, JR., *Bogart, Georgia*

This chapter considers: (1) basic principles of oxygen use within the body and factors that influence oxygen delivery (DO_2) to cells pertinent to supplemental oxygen therapy; (2) indications for delivering supplemental oxygen; (3) methods of providing supplemental oxygen and the effectiveness of each approach; (4) methods of determining effectiveness of oxygen supplementation; including interpretation of blood gases; (5) guidelines for managing dysoxic patients that do not respond favorably to oxygen supplementation; and (6) an overview of a special form of supplemental oxygen delivery involving the use hyperbaric chambers.

BASIC PRINCIPLES OF OXYGEN DELIVERY AND USE

Oxygen is necessary for all normal metabolic processes involving cellular function. If DO_2 is insufficient to meet the needs of cells, particularly those with high metabolic rates as indicated by high oxygen consumption (VO_2), the resultant *dysoxia* causes a measurable decrease in adenosine triphosphate (ATP) production within a matter of seconds. Over 90% of generated ATP is used to maintain plasma membrane function and integrity. Dysoxia begins affecting overall cell function immediately. If these cells are cerebral neurons or myocardial cells, severe dysoxia can lead to irreversible dysfunction and death within minutes. If the cells are enterocytes, dysfunction can lead to death within hours as a result of mucosal barrier dysfunction, the consequences of endotoxin and bacterial absorption. In wounds dysoxia is associated with an increase in infection rates and prolonged healing time.

FACTORS THAT INFLUENCE CELLULAR OXYGEN DELIVERY

Oxygen is delivered to the cells in two forms: that dissolved in the arterial blood (and responsible for the diffusion pressure driving oxygen to tissues), and the remaining 97% that is attached to hemoglobin.

The most important factors influencing this amount of oxygen in the blood are the amount or concentration (g%) of hemoglobin in the blood (Hb) and the percentage of the hemoglobin that is saturated with oxygen (SaO_2). The amount of oxygen dissolved in plasma can be measured as the partial pressure of oxygen (pO_2). It is this partial pressure of oxygen that provides the diffusion gradient responsible for movement of oxygen into the interstitial space and cells. The formula for the total content of oxygen in arterial blood (CaO_2) is

$$\text{CaO}_2 = (1.34 \times [\text{Hb}] \times \text{SaO}_2) + (\text{PaO}_2 \times 0.0031)$$

There is a direct although nonlinear relationship between the SaO_2 and the PaO_2 in the blood. Supplemental oxygen increases the partial pressure in the alveolus, which in turn raises the partial pressure of oxygen (PO_2) in the blood. A hemoglobin concentration of 10g/dl (packed cell volume of 30%) is probably optional for most critical patients provided cardiac output (CC) and microcirculatory flow are adequate. Although the majority of oxygen is transported in the blood via hemoglobin, the PaO_2 in the plasma provides the diffusion gradient creating uptake (saturation) and downloading of oxygen onto the hemoglobin molecule. DO_2 is also determined by the PO_2 within the alveoli, pulmonary capillary blood flow, matching of ventilation and perfusion in the lungs, and delivery of blood to the microcirculation. Delivery of blood to the microcirculation is determined by cardiac output (CO) and functional capillary density and the amount of interstitial space present between the capillary and the cell. Functional capillary density is influenced by both precapillary and postcapillary tone and surrounding interstitial space pressure and distance. Interstitial space *distance* is that between the capillary and the tissue cells. This space or distance is increased with interstitial edema.

INDICATIONS FOR PROVIDING SUPPLEMENTAL OXYGEN

Any clinical condition that negatively affects oxygen intake, uptake across the pulmonary capillary, CO blood flow (pulmonary or systemic), microcirculatory flow, capillary density, and oxygen transport through the interstitial space can negatively influence DO_2 . Any of these disorders may constitute an indication for supplemental oxygen.

The American College of Chest Physicians and the National Heart Lung and Blood Institute recommendations for instituting oxygen therapy are cardiac and respiratory arrest; hypoxemia ($\text{PaO}_2 < 7.8 \text{ kPa}$, $\text{SaO}_2 < 90\%$), hypotension (systolic blood pressure $< 100 \text{ mm Hg}$); low cardiac output and metabolic acidosis (bicarbonate $< 18 \text{ mmol/L}$); and respiratory distress (respiratory rate $> 24/\text{min}$). Their guidelines for initial oxygen dose are cardiac or respiratory arrest 100%, and hypoxemia 40% to 60%.

The SaO_2 and PaO_2 are the main clinical indicators for initiating, monitoring, and adjusting oxygen treatment. However, PaO_2 and SaO_2 can be normal when tissue hypoxia is caused by low output cardiac states, anemia, or failure of tissues to use oxygen. In these circumstances, mixed venous oxygen partial pressure (PvO_2), which is measured in pulmonary artery blood, is a better measure of tissue oxygenation. A third choice is to sample blood from a central venous catheter. Even in the presence of a normal PaO_2 and PvO_2 , *severe hypoxia in a single organ may result in death. Supplemental*

oxygen may be a deciding factor in these cases. Measurement of individual tissue oxygenation is difficult, requiring specialized techniques, including tonometry and oxygen probes.

Recent studies have proven that providing supplemental oxygen to animals in hemorrhagic shock *prior* to blood and fluid replacement decreases the amount of reperfusion injury over those not given supplemental oxygen beforehand (Meier et al., 2004). Elevating the fractional percent of inspired oxygen (FiO_2) from 0.2 to nearly 1 in hemorrhagic shock elevated brain oxygen tension (PbrO_2) from a baseline of 15 mm Hg to 36 mm Hg; when ventilation was added, PbrO_2 increased to 88 mm (Manley et al., 1999). Research also has proven that providing supplemental oxygen after major surgery is associated with a decrease in wound infection rate. In one study involving 500 humans who underwent colorectal resection, the wound infection rate had decreased from 11.2% to 5.2% when supplemental oxygen was added (Greif et al., 2000). Tissue oxygen tensions are 10 to 20 mm Hg higher when supplemental oxygen is provided (Whitney et al., 2001).

The need for supplemental oxygen treatment can induce: (1) *history and physical findings* indicating dysoxia (Box 137-1); (2) a *physical condition* that has been shown to benefit from supplemental oxygen (Box 137-2); (3)

monitoring abnormalities that develop because of the lack of oxygen in the tissues (Box 137-3), or (4) *laboratory abnormalities* that indicate either low oxygen tension or the consequence of such (Box 137-4). Although pulse oximetry is commonly used to determine the need for oxygen supplementation, it can be unreliable because there are times when this monitoring device yields false information. Blood gas determinations, especially arterial PO_2 , are the gold standard used to determine the need for oxygen supplementation. Values below 80 mm Hg indicate the need for supplemental oxygen. Because arterial samples can be more difficult to obtain, venous samples also have been used in critical patients to assess oxygenation. Venous PO_2 values are influenced by the amount of oxygen in the arterial blood, tissue perfusion, and uptake of oxygen into the tissues (oxygen extraction ratio). If venous PO_2 is below 30 mm Hg, this indicates either that arterial oxygen levels were low or that the blood flow and tissue perfusion is inadequate (creating a high oxygen extraction ratio). In either case supplemental oxygen is indicated.

If arterial blood PO_2 is below 80 mm Hg and partial pressure of carbon dioxide (PCO_2) is greater than 50 mm Hg, there is a need to support the patient's ventilation

Box 137-1

Clinical Signs of Dysoxia

- Restlessness
- Anxiousness
- Increased breathing rate and effort
- Frantic behavior
- Increased breath sounds, adventitious sounds
- Use of accessory muscles with each breath
- Struggling efforts with breathing
- Light discoloration of mucous membranes
- Cyanosis
- Gasping
- Darkening cyanosis, poor refill time
- Unconsciousness
- Seizurelike activity

Box 137-3

Common Physiologic Monitoring Abnormalities That May Indicate Dysoxia

- Electrocardiogram (ST segment changes, arrhythmias, tachycardia, bradycardia)
- Arterial blood pressure (below 80 or above 150 systolic)
- Arterial pulse pressure (difference between systolic and diastolic less than 30)
- Doppler flow (weak, feeble sounds or very bounding sounds)
- Toe web temperature: rectal temperature differential (greater than 10°F)
- Rectal or aural temperature (above 104°F)
- Pulse oximetry (values below 92%)
- Central venous pressure (values below 3–4 cm H_2O)
- Urinary output (values below $\{1/4\}$ ml/kg/hr for cats, below $\{1/2\}$ ml/kg/hr for dogs)

Box 137-2

Physical Conditions That May Benefit From Supplemental Oxygen

- Trauma
- Sepsis
- Heart disease (failure)
- Neurologic diseases
- Head injury (early supplemental oxygen decreases secondary brain injury, edema, neuronal death)
- Shock (all types)
- Pulmonary edema (all causes)
- Severe wounds
- Surgical wounds
- Pancreatitis
- Snake and spider bite

Box 137-4

Common Laboratory Monitoring Abnormalities That May Indicate Dysoxia

- Reduced hematocrit (any acute drop of 10 or any value below 30)
- Low total plasma solids (any acute drop of 0.6 or greater, before fluid support)
- Low partial pressure of venous oxygen (any levels below 30 mm Hg)
- Low partial pressure of arterial oxygen (any levels below 80 mm Hg)
- Low partial pressure of capillary oxygen (any levels below 45 mm Hg)
- Base deficit (minus 6)
- Elevated, blood lactate (greater than 3 mmol/L)

in addition to providing supplemental oxygen. If the patient does not respond favorably to supplemental oxygen with a decrease in respiratory effort and rate, additional treatment may be useful. This is done using a “tight-fitting” mask, and providing positive-pressure ventilation (PPV) with the use of a bag-valve (AMBU bag). The reservoir is connected to a flow of oxygen (5-15 L/min) to keep the attached reservoir bag partially full (providing nearly 100% oxygen). The addition of a positive end-expiratory pressure (PEEP) valve on the exhalation port of the AMBU bag will increase pulmonary functional residual capacity (FRC) and decrease the work of breathing. This is recommended in patients with pulmonary edema, severe intrapulmonary hemorrhage, and any other lung parenchyma diseases that lead to ventilation-perfusion mismatching. Mild sedation may be required for the patient to accept a mask. A recommended sedative combination is intramuscular or intravenous acepromazine (0.005 to 0.01 mg/kg), butorphanol (0.1 to 0.2 mg/kg), and, if necessary, ketamine (1 to 4 mg/kg) starting at the lower dosages. If auscultation suggests a pneumothorax with decreased breath sounds, thoracentesis should be performed, and any free air removed. Insertion of a chest tube is necessary if a negative vacuum is not reached. In extreme cases a tracheotomy or the use of a neuromuscular blocker such as succinylcholine with deeper sedation and laryngoscopic-assisted tracheal intubation is needed to provide adequate ventilation and oxygenation. Cases that may need this care include acute aspiration, fulminate pulmonary edema from many etiologies, pneumonia, or severe intrapulmonary hemorrhage.

Common clinical conditions indicating the need for oxygen supplementation include the following:

- Pulmonary edema from any cause
- An acute drop in hemoglobin concentration to less than 9 g/dl with clinical signs of anemia
- An acute decrease in CO, including that due to cardiac tamponade
- Blood volume loss
- Significant localized interstitial space edema secondary to a severe wound, which causes a decrease in oxygen tension to tissues at the wound site
- Head and spinal cord injury

Any acutely ill or injured patient has an increased demand for oxygen and removal of carbon dioxide (CO₂) because of the higher metabolic rates of the cells. Clinical indications of increased oxygen demands include increases in respiratory rate, respiratory effort, heart rate, blood flow (assessed by Doppler), blood pressure, body temperature, decreased capillary refill time, and bright mucous membranes. When these are noted, it can be concluded that VO₂ and CO₂ production is greater than normal.

METHODS USED TO SUPPLY SUPPLEMENTAL OXYGEN

Supplemental oxygen can be provided by a number of delivery methods, both noninvasive and invasive.

Blow-By Oxygen

This is most easily provided by using small-diameter oxygen tubing that is connected directly to the oxygen source. The end of the tube is placed in front of the patient's nose or mouth. The flow rate generally varies from 3 to 15 L/minute. A small nozzle, such as a 14g IV catheter attached to the patient end of the oxygen tubing, creates a jet that will be especially effective in a patient with small restricted airways. It may also decrease the work of breathing. A mask can also be used but is usually not well tolerated, especially if the patient is panting.

Oxygen Hood

Many animals tolerate having their heads placed inside a plastic bag as a temporary treatment method. The oxygen tubing is placed through a small hole in the front of the bag, and the back of the bag is left open to allow gas to escape. This is particularly useful in the obtunded patient because high concentrations of oxygen can be provided (85% to 95%) (Engelhardt and Crowe, 2004), while allowing other procedures to be performed (e.g., blood drawing, placement of catheters, x-rays). Oxygen hoods may not be tolerated by the panting dog since the hood may become rapidly overheated and overhumidified. In these cases it is necessary to sedate the dog or use an oxygen collar. The temperature of the inside of the hood should be checked periodically.

Oxygen Collar

An oxygen canopy device can also be made by covering the ventral 50% to 75% of an Elizabethan collar with plastic wrap (Crowe, 2003a; Engelhardt and Crowe, 2004). This can be used for long-term therapy, but mild sedation may be required for some patients to tolerate it. The Elizabethan collar should be one size larger than would normally be used for the patient. The oxygen tubing is placed along the inside of the collar and taped in place ventrally. Oxygen concentrations of up to 80% generally can be achieved. Flow rates of approximately 1 L/10 kg of body weight usually provide an adequate inspired FiO₂. Flow rates should be adjusted based on clinical response to the oxygen supplementation and patient comfort. In heavily panting dogs, the plastic in the front of the collar may have to be decreased to only just above the nose. No humidification should be added in these situations. Use of a commercial collar that is zipped up in front, completely covering the opening, has been associated with over-heating, and if used, it should only cover a portion of the collar. Since oxygen is heavier than room air, the coverage should be started at the ventral aspect of the collar. To measure the amount of oxygen in the collar an oxygen analyzer (example: MiniOx-I Oxygen Analyzer, MSA Medical Products) is recommended. Minimum FiO₂ for chronic conditions is 35% to 40% and for acute or emergency conditions is 60% to 90% or above and by adding a small strip of plastic wrap over the ventral half of the collar, oxygen levels will be increased to greater than 60% (FiO₂ 0.6).

Nasal Cannula

Most dogs and cats tolerate short human nasal cannulas. These have two sections of tubing extending from a small nose piece that is attached to flexible oxygen tubing shaped into a loop that can be slipped behind the patient's head. They come in three different sizes: infant, which is used for the cat and small dog (2 to 5 kg of body weight); pediatric, which is used for the medium-sized dog (11 to 24 kg); and adult, which is used for the large dog (>25 kg). A few drops of proparacaine or lidocaine are first placed into each nostril. If the patient objects significantly, stress and struggling should be reduced by sedation with a mixture of ketamine, butorphanol, and acepromazine (as described previously). After waiting a few minutes for the sedation and local anesthetic to take effect, the tips of the cannula are placed into the nostrils, and the tubing is brought to each side of the nose and secured with skin staples. The tubing is continued behind the patient's head, and the loop is tightened where the loop comes together. The continuation of the flexible oxygen tubing is secured with tape around the patient's neck or chest to prevent tension on the nostrils. The tubing is attached to a source of humidified oxygen. Oxygen is then delivered to the system at 50 to 100 ml/kg up to a maximum rate of 5 to 6 L/minute. This provides at least a 40% nasal oxygen concentration. As with other types of nasal tubes, these patients should have an Elizabethan collar in place if they start to bother the catheter.

Nasal Catheters

This is one of the most effective ways to provide oxygen (Fitzpatrick and Crowe, 1986). A narrow-bore red rubber tube (3.5 to 8 Fr) is placed in the ventral nasal meatus and sutured or glued to the patient's face. For small patients 3.5- to 5-Fr tubes are used. For medium-sized dogs 5- to 8-Fr tubes are used, and for larger dogs 8-Fr tubes are placed. Several drops of 0.5% proparacaine ophthalmic solution are instilled in the nose. Lidocaine also can be used. If lidocaine is being used in cats, the dose should be monitored to ensure that a toxic level is not reached. A small amount of sterile water-soluble gel or lidocaine gel placed on the outside of the tube facilitates passage of the tube. If the patient objects to placement, sedation (see prior section) should be considered.

The nasal catheter typically is measured from the tip of the nose to the lateral canthus (nasopharyngeal). In cats the tube readily passes into the nasal meatus. Pushing the nasal planum of the dog dorsally (not needed in cats) and directing the tube ventromedially should enable the tube to pass easily into the ventral meatus. The tube is sutured close to the nostril (maximum 0.5 cm from the nares). This suture is very important. A second suture is placed on the lateral aspect of the face or on the bridge of the nose between the eyes. Nasal oxygen should be avoided in the patient with severe nasal or pharyngeal disease or in the patient with severe thrombocytopenia, a bleeding disorder, or head trauma. Sneezing elevates intracranial pressure, and nasal tubes should be avoided if this is a concern.

At flow rates of 50 ml/kg/min in small dogs and cats and 100 ml/kg in larger dogs the FiO_2 is approximately 0.4 to 0.5. If higher flow rates are desired, a second tube can

be placed in the other nostril, or the tube can be placed deeper as a nasotracheal oxygen catheter. For *nasal-nasal* catheters the nasal catheter tip ends with the tip in the middle of the nose. For *nasopharyngeal* catheters the catheter tip ends in the proximal pharynx, which corresponds to the angle of the mandible. The oxygen administered by this method typically provides 60% to 70% oxygen at the same flow rates as nasal catheters, which provide 40%. If the patient is swallowing a lot of air, providing oxygen in this manner may contribute to gastric overdistention; thus the patient should be monitored closely. For *nasotracheal* oxygen catheters the catheter tip ends in the proximal tracheal lumen. Oxygen provided by this method provides 80% to 90% oxygen at 50% of the same flow rates of those of nasal catheters. With nasotracheal catheters the tube is measured to the level of the thoracic inlet or further to the tracheal bifurcation or the fifth intercostal space if indicated. The patient's head should be held in an extended position to facilitate blind passage into the trachea. If coughing is noted, lidocaine can be infused via the tube to anesthetize the larynx. Nasotracheal oxygen is a very useful in the patient with laryngeal dysfunction or collapsing cervical trachea. Oxygen should be delivered into the trachea at rates of 50% of that used for nasal catheters. The oxygen should always be humidified, except under emergency conditions; then the duration of unhumidified oxygen should be as short as possible.

Transtracheal Catheters

In the patient who has an upper airway obstruction transtracheal oxygen can be provided on an emergent basis. This route also can be used as an alternative to nasal routes (Mann et al., 1992). A large-bore over-the-needle catheter or commercially available tracheal catheter can be placed between tracheal rings in the midcervical region. An adaptor is attached to the catheter and connected to oxygen. A 14-g intravenous catheter attached to a syringe can be inserted into the cricothyroid membrane or between tracheal rings and into the airway. The syringe plunger is then pulled back to verify that the tip of the catheter is in the airway (since air will be easily aspirated). The catheter is advanced, and the needle portion removed. Humidified oxygen can be delivered by an intravenous administration set improvised to attach to the catheter hub with the male end of the set. The "spike" end of the administration set is attached to the oxygen-humidifier system. A 3-mm endotracheal tube connector can then be inserted into the hub of the catheter, and oxygen and ventilation provided by the use of a resuscitator (AMBU) bag. Ventilating at a very rapid rate (150 breaths per minute) with oxygen attached and using the resuscitator bag with a reservoir attached provides adequate stop-gap ventilation and oxygenation (Crowe, 2003a).

Oxygen Cages

Oxygen cages are commonly used because it is very easy to deliver supplemental oxygen in this way. However, oxygen cages have several drawbacks. First is the length of time it takes to get the oxygen concentration up to a level that will help the patient (Engelhardt and Crowe, 2004). It can take 30 minutes to reach a 45% oxygen

concentration at 15L/minute and 45 minutes to reach a 60% concentration. The oxygen concentration may never exceed 30% at the 5-L/minute rate. The second problem with the use of oxygen cages is the inability to evaluate or physically treat the patient. Only visual observation is possible. The third problem occurs when the oxygen cage is opened to perform and evaluate treatment: the oxygen level within the cage drops substantially (generally from .4 to .2). This can lead to significant patient anxiety and respiratory compromise because the patient is now "back to room air," which occurs fairly suddenly. Animals that have been receiving significant relief of their dysoxia from the supplemental oxygen are at risk for cardiovascular collapse while they are being handled. The fourth problem is cost—of the cage itself and also of the oxygen. From my experience and those of many others, most oxygen cages require at least a 10L/minute flow rate to maintain a 40% oxygen concentration. Even if the cage is door is not opened frequently, which is unlikely in critical cases, the oxygen cost is approximately 10 times that for the same patient with nasopharyngeal oxygen in place.

We have investigated the effectiveness of other non-invasive methods to provide supplemental oxygen (Engelhardt and Crowe, 2004). Oxygen flow rates of 5 and 15L/minute were used to evaluate various methods of delivery (i.e., plastic sheeting placed over a standard commercial cage, plastic sheeting placed over the top of a standard size "book box" cardboard box, clear plastic anesthesia "cat" box, a Crowe-oxygen collar [an E-collar one size too big fitted in front with a section of clear plastic wrap that covered the bottom half of the collar], blow-by oxygen, and a plastic bag hood [allowing the oxygen to flow out from the bottom]). The hood and the Crowe collar reached maximum oxygen concentrations of 85% within 1 minute from the onset of oxygen flow of 5L/min. Other modalities of supplying supplemental oxygen also have been investigated, including the use of human nasal cannulas (infant, pediatric, and adult), nasal tubes (unilateral or bilateral), nasopharyngeal tubes, nasotracheal tubes, cricothyroid tubes, and tracheotomy tubes. The FiO_2 commonly obtained in the shortest period of time were nasal catheters (single) 45% in 2 minutes; nasal cannulas 60% in 1 minute; bilateral nasal catheters 85% within 2 minutes, nasopharyngeal catheter 85% in 2 minutes using 3-L flow rates; nasotracheal tube 85% in 30 seconds; transtracheal catheter nearly 100% within 30 seconds when 5-L/minute flow rates were used.

DETERMINING SUPPLEMENTAL OXYGEN EFFECTIVENESS

The effectiveness of supplemental oxygen is determined by clinical evaluation, pulse oximetry, and measurement of arterial blood gases.

Clinical Evaluation

This is the most common and most relied on approach. The amount of change in respiratory effort and the speed that it occurs once oxygen supplementation is begun are noted. It is hoped that both respiratory rate and effort are drastically reduced and that this reduction is observed

within 20 minutes of starting oxygen supplementation. Other favorable responses may include restoration of calmness, a decrease in heart and pulse rate to normal, a return of normal blood flow (as determined by Doppler methods), and normalized blood pressure (as determined by either direct or indirect methods). Other methods of clinical evaluation include changes in blood lactate levels, strength of cardiac contractions or aortic velocity time integral as observed by echocardiography, and resolution of electrocardiographic abnormalities.

Pulse Oximetry

Pulse oximetry involves the measurement of the peak oxygen saturation of hemoglobin in capillary blood. Many factors can influence pulse oximeter accuracy; blood flow, probe contact, extraneous light, pigment, and movement are common causes for measurement inaccuracies. If these can be minimized, clinical studies have shown the methodology to be accurate and effective in the clinical detection of global dysoxia. Probes are usually placed on tissue beds that can be analyzed readily. Transmission probes include the tongue, toe webbing, ear pinna, and lip; reflectance probes include the esophagus and rectum. Units that provide a graph of the pulse contour are preferred over those that just provide a bar showing signal strength. Any saturation of peripheral oxygen (SpO_2) value below 92mm Hg indicates an amount of oxygen desaturation that warrants oxygen supplementation; the lower the value, the greater the need for oxygen.

Arterial Blood Gas

This method hinges on the ability to obtain an arterial blood sample of sufficient volume to allow testing of the PO_2 . Ventilation effectiveness can also be evaluated by analyzing the PCO_2 . Arterial PO_2 should be at 65mm Hg or above. A PaO_2 value below 65 mm Hg in spite of oxygen supplementation indicates a right-to-left shunt or severe pulmonary dysfunction and the need to consider positive-pressure ventilation. Other possible causes of unresponsive PaO_2 include pneumothorax, severe hypovolemic shock, cardiogenic shock, and obstructive airway disease.

CARE OF DYSOXIC PATIENTS NOT RESPONDING TO SUPPLEMENTAL OXYGEN

Response to supplemental oxygen therapy usually can be gauged by monitoring respiratory rate and effort, presence of cyanosis, and pulse oximetry readings. If the patient does not respond to supplemental oxygen, anesthesia, intubation, and ventilation should be strongly considered. As an intermediate step, assisted ventilation with the use of sedation followed by placement of a tight-fitting mask and positive-pressure support ventilation timed with each patient breath can be tried. It is important to recognize that patients who have been working hard to breathe for an extended period of time may die from ventilatory failure secondary to exhaustion. Simply sedating the patient generally allows the placement of a AMBU bag attached to a reservoir and oxygen supply, delivering oxygen at

5 to 15L/min. The mask is applied firmly with the patient's head and neck extended (with the tongue pulled out and the mouth closed over the extended tongue (if the patient allows). The bag is squeezed with inhalation, thus assisting the patient with positive-pressure breathing. Timing each squeeze of the bag with the beginning of each breath may relieve the patient's respiratory difficulty before anesthesia and intubation. Administration of a mixture of ketamine (5 mg/kg) and diazepam (0.25 mg/kg), given to effect, generally allows tracheal intubation. Other drugs can be used such as 2.5% thiopental (5 to 10 mg/kg) and propofol (3 to 8 mg/kg), but in my experience these produce more significant cardiovascular depression and are not my drugs of choice. Etomidate also can be used. It is especially useful as part of a rapid sequence induction anesthesia or for conscious sedation. It has a rapid onset of action and a low cardiovascular risk profile. The dose ranges from 0.025 mg/kg for sedation to 0.05 to 0.25 mg/kg for rapid anesthesia induction, with an average of 0.1 mg/kg for the moderately compromised patient. Neuromuscular blockers (succinylcholine 0.01 mg/kg intravenously [IV] or atracurium 0.25 mg/kg IV) can also be used after ketamine, diazepam, or an opioid are given (atracurium is preferred over succinylcholine because it does not cause muscular contractions). In the compromised patient doses should always be titrated because much less drug is generally required than is needed for the healthy patient. Once intubated (preferably with a laryngoscope since this provides for less laryngeal manipulation and reduced vasovagal response), positive-pressure ventilation is continued. Sedation for ventilatory support can be achieved with a continuous rate infusion of various drugs. These include sodium pentobarbital (1 mg/kg/hr), hydromorphone (0.1 mg/kg/hr with ketamine 2 mg/kg/hr, or 1 mg/kg/hr with the addition of lidocaine 3 mg/kg/hr). There are many other combinations that can be used. Institution of positive pressure ventilation is most often made very late in the stages of respiratory failure. I highly recommend positive pressure ventilatory support with PEEP early in the course of the disease.

Bag-Valve-Mask Continuous Positive Airway Pressure Ventilation

Continuous positive airway pressure (CPAP) is defined as maintaining the pressure above atmospheric pressure throughout the respiratory cycle. A modified form of CPAP can be provided to most awake (but sedated) dogs and cats using the interim method for patient support discussed previously. A tight-fitting mask attached to an anesthetic circuit or an AMBU bag is placed on the patient. The pop-off valve of the anesthetic machine is tightened down, and the oxygen flow rate is increased until the pressure on the circuit at end-exhalation registers 5 cm H₂O. Alternatively a positive end-expiratory pressure (PEEP) valve is added to the exhalation port of the AMBU bag. The patient breathes spontaneously while oxygen under pressure is delivered during inspiration by manual squeezing of the AMBU bag. This decreases the work of breathing and also improves gas exchange by increasing functional residual capacity. This also acts to mobilize edema fluid. It is one way to effectively treat acute respiratory failure secondary to pulmonary injury,

edema, and intrapulmonary hemorrhage. Applied more frequently at lower tidal volumes, it is helpful for patients with a diaphragmatic hernia and as a means of preoxygenating patients before attempting tracheal intubation and ventilation (Crowe, 2003b).

Ventilatory Support and Positive End-Expiratory Pressure

Ventilatory support is required for at least several hours (minimum) in most patients who remain hypoxemic despite oxygen supplementation or in patients who have an impaired ability to exhale CO₂ (PaCO₂ >50 mm Hg). As a rule of thumb patients should be ventilated at 10 to 20 breaths per minute at tidal volumes of 5 to 10 ml/kg (up to 15 to 20 ml/kg). Peak inspiratory pressures should try to be kept below 15 to 17 mm Hg whenever possible to reduce the likelihood of barotrauma. Ventilatory parameters (tidal volume and respiratory rate) should be adjusted based on capnometry and/or blood gases or, if these are unavailable, to the point of patient compliance at which the patient does not "fight" the positive-pressure breaths provided. When patients require high peak inspiratory pressures, PEEP should be added. Alveoli are prevented from collapsing when PEEP is used; use of PEEP increases the functional residual capacity, which leaves air in the lungs a little longer, increasing the time for gas exchange. This often allows peak inspiratory pressures to be decreased. As a rule of thumb it is recommended to begin PEEP at 5 to 10 cm H₂O. Excessive PEEP (>15) itself can cause barotrauma; thus this should be used only if necessary (continued PaO₂ below 60 mm Hg, SpO₂ below 80% or visible cyanosis). The major side effects of PEEP are an increase in intrathoracic pressure, which can decrease venous return to the heart and an increase in dead space. Once initiated, ventilation with PEEP is often needed for multiple hours to multiple days (see next chapter).

Patients Requiring Supplemental Oxygen That Must Be Transported

Patients needing oxygen may require 24-hour care. If a patient must be transported to another facility, it should be sent on oxygen. This is best provided with the use of a small oxygen cylinder attached to a flowmeter/regulator that can be purchased for approximately \$80.00 from many emergency medical services suppliers (Galls)(Crowe, 2003a). If a tank and regulator are not available, most local home flowmeter/medical supply businesses or oxygen suppliers provide small oxygen tanks at very little cost. A regulator can be rented for minimal expense, although on occasion a deposit may be required. Many of these services have 24-hour availability.

HYPERBARIC OXYGEN: APPLICATION IN WOUNDS AND OTHER DYSOXIC CONDITIONS

Oxygen tension in wounds plays a significant role in healing and the potential for necrosis and infection (Crowe, 2002; Greif et al., 2000; Whitney et al., 2001). As measured by microelectrodes, the wound space is initially hypoxic

(PO₂ 0 to 15 mm Hg), hypoglycemic (2 to 4 mM), acidotic (pH 6.5 to 7.2), hyperkalemic (5.5 to 7.5 mM), hyperlactic (50 to 120 mM), and hypercarbic (60 to 90 mm Hg). Part of this unusual environment is caused by activated macrophages. A pH as low as 3.7 has been measured on the surface of activated macrophages. At the edge of a wound where there is viable circulation, PO₂ has been measured at 40 mm Hg. Oxygen is rapidly consumed as it diffuses from the edge of the viable capillaries into the wound space. Within 100 to 150 microns PO₂ can approach zero. Local tissue hypoxia has also been documented in surgical wounds when tight sutures impair local microcirculation. The tissue hypoxia is associated with a decreased oxidation-reduction potential, and this promotes tissue death and necrosis. The low pH also is associated with decreased polymorphonuclear (PMN) leukocyte function (Whitney et al., 2001). These conditions promote anaerobic and microaerophilic bacterial growth. The bacteria may be introduced by way of outside contamination or from an endogenous source (i.e., the gastrointestinal tract). In infections associated with an aerobic and anaerobic bacteria there may be bacterial synergism in which the growth of the aerophilic or microaerophilic bacteria further lowers the pH, allowing the growth of the more fastidious anaerobes to accelerate rapidly. The wound environment with bacterial growth involved becomes even more hypoxic. In bacterial osteomyelitis PO₂ of bone is lowered by 50%. One of the best ways to stop this vicious cycle is to provide oxygen to the wound, especially if it can be provided under hyperbaric conditions (pressures higher than sea level).

Oxygen given under hyperbaric conditions diffuses into the wound much more efficiently and may also be "stored" in the ground substance of the interstitial space. Treatments of hyperbaric oxygen are 1 to 2 hours in length and are done once or twice daily for a series of 3 to 15 days or more, depending on the wound condition. Chronic wounds or those involving an infection in the bone or dense connective tissues such as ligaments or tendons require the longer treatment times. In acute wounds even one treatment may be beneficial in preventing tissue death from ischemia or infection.

There are various ways of providing oxygen at hyperbaric conditions. One method is by simply placing the involved limb or area of the body into a pouch that becomes fairly airtight and then filling the pouch with oxygen. These "bags of oxygen" are mildly effective in raising oxygen tensions in wounds; however, problems with leakage and the need for sedation minimize potential value. If the wound is inflamed, the pressure may induce pain.

The second method, which I use very frequently, is to use a low-pressure monoplace chamber. The animal is placed into this chamber, which is made of a high-density flexible synthetic clothlike material. The chamber is filled with air using two compressors that increase the pressure to 1.25 to 1.3 atmospheres (3.5 to 4.5 pounds per square inch [PSI] greater than sea level). Most of the time the animal is mildly sedated. In some cases an oxygen Crowe collar is applied to increase oxygen concentrations to 60% to 80% as described previously.

The third method involves the placement of the animal in a chamber made of stainless steel, Plexiglas, or Mylar in which 100% oxygen is used to pressurize the

chamber. Pressures are increased from 11 to 15 PSI, which corresponds to 1.8 to 2.1 atmospheres. In most chambers the amount of oxygen needed to produce a treatment of 1 hour at 15 PSI requires about 2300L of oxygen. The higher-pressure chamber is able to elevate the PO₂ in tissues much higher than low-pressure chambers (i.e., 1560 mm Hg of oxygen with the high-pressure chamber versus 600 mm Hg of oxygen with the lower-pressure, lower-concentration [60%] chamber). This appears clinically most important when infections involve anaerobic or microaerophilic organisms or when wounds or tissues have significant edema present (Crowe 2000, 2002a, b).

Experimental and clinical investigations of wounds that have been treated with hyperbaric oxygen reveal that wound infections are prevented. Antibiotic effectiveness in infected wounds is increased as PMN and macrophage function is also increased. Edema in wounds is lessened significantly, allowing for better blood flow and DO₂ that continues following the hyperbaric oxygen therapy (HBOT). Lymphatic flow is increased, and pain is lessened as the edema and dysoxia dissipate. Wound healing rates also speed up as the oxygen stimulates fibroplasia and osteon proliferation. Pain and inflammation are lessened with HBOTs. The wound bed is much more oxygenated, and tissue that is necrotic is defined quicker with the use of HBOTs. Pain is lessened from decreasing edema and hypoxia at nerve endings. Other potential indications include pancreatitis, aortic thrombosis, acute cortical blindness, fibrocartilaginous embolus, and acute intervertebral disk herniation. Further investigations are required to elucidate the clinical conditions that may benefit from the use of hyperbaric oxygen therapy. Box 137-5 is a summary of the various diseases that I have treated with hyperbaric oxygen with clinical benefits noted (Crowe 2000, 2002a).

Box 137-5

Possible Indications for Hyperbaric Oxygen Therapy

- Brain and spinal cord edema, injury, trauma
- Post intervertebral disk herniation, fibrocartilage embolus
- Pancreatitis
- Abdominal sepsis, bowel obstruction, postgastric dilation volvulus
- Pyothorax
- Posttraumatic or ischemic shock
- Postcardiopulmonary resuscitation neurologic impairment
- Acute cortical blindness
- Swollen limbs and joints following trauma, orthopedic surgery
- Severe sinusitis, septic rhinitis
- Aortic thromboembolism
- Vestibular syndrome
- Suspected stroke
- Severe wounds
- Infected wounds
- Chronic ulcers (gastrointestinal)
- Chronic delayed unions
- Bad complex fractures
- Postradiation necrosis
- Snake and spider bite

CHAPTER 138

Ventilator Therapy

SHANE W. BATEMAN, *Columbus, Ohio*
ELIZABETH O'TOOLE, *Oakville, Ontario, Canada*

Patients with respiratory failure should receive assisted ventilation with a modern positive-pressure ventilator designed for that purpose. The aims of mechanical ventilation are to improve gas exchange and to decrease the work of breathing in patients with a reversible underlying disease process. Ventilators designed for use in anesthesia are not suitable for ventilating critically ill patients because they typically cannot regulate the oxygen concentration. Prolonged delivery of high oxygen concentrations can cause toxicity and worsen lung injury. Critical care ventilators are also more complex than ventilators designed for use in anesthesia and include a variety of modes for applying positive-pressure ventilation, allowing specifically tailored respiratory therapy.

It is a common fallacy that patients who require mechanical ventilation are doomed to die. Two factors have contributed to this fallacy: a previous lack of understanding of the special requirements for ventilating lung-injured patients and a tendency to initiate ventilation too late in the course of disease as a "last-ditch attempt" when patients typically have been hypoxemic and hypercarbic

for some time. The pathophysiologic consequences of these two factors are significant and should not be underestimated. Ventilator care has an important place in the management of carefully selected critically ill patients.

DEFINITION OF RESPIRATORY FAILURE

Although a strict definition of respiratory failure, and thus the requirement for ventilatory care, is not universally agreed on, the following blood gas guidelines are appropriate to identify inadequate gas exchange or hypoventilation:

- Arterial partial pressure of carbon dioxide (PCO_2) above 50 mm Hg
- Arterial partial pressure of oxygen (PO_2) will not rise above 50 mm Hg on a test dose of 100% O_2 , or arterial PO_2 cannot be maintained above 50 mm Hg with fractional percent of inspired oxygen (FiO_2) of 0.6 or less

In addition to these blood gas guidelines, the work of breathing needed to maintain current gas exchange must be critically assessed for each patient. This assessment is

subjective and based on clinical judgment. Respiratory muscle exhaustion can occur rapidly and may precede respiratory failure and sudden death. The decision to initiate mechanical ventilation should be based on evidence of both the failure of gas exchange and the work of breathing.

INDICATIONS FOR MECHANICAL VENTILATION

In the past, many clinicians have associated the use of mechanical ventilation with certain death. Unfortunately this historic attitude is still prevalent, and mechanical ventilation is often undertaken too late. Mechanical ventilation may be unsuccessful in some cases simply because the opportunity to successfully treat the patient's condition has already passed. With the improvements in diagnostic, supportive, and monitoring technology in veterinary critical care, this attitude needs to be readdressed. Mechanical ventilation frequently is successful in treating veterinary patients with respiratory failure provided patients are chosen carefully, appropriate ventilation strategies are chosen, and the decision to initiate mechanical ventilation is made early in the course of disease.

Several authors have offered the following thoughts about the place of mechanical ventilation in critical care.

- The indication for intubation and mechanical ventilation is THINKING of it.
- Artificial airways are not a disease; ventilators are not an addiction.
- Intubation is not an act of weakness; it is an act of kindness.

Two classifications of patients benefit from mechanical ventilation: those with primary pulmonary pathology (lung-injured patients), and those with neuromuscular apparatus failure (nonlung-injured patient). Examples of primary respiratory pathology include noncardiogenic and cardiogenic pulmonary edema; pneumonia; pulmonary contusions; and acute lung injury, including acute respiratory distress syndrome (ARDS), upper and lower airway obstruction, and smoke inhalation. Examples of neuromuscular apparatus failure include polyradiculoneuritis (coonhound paralysis), myasthenia gravis, tick paralysis, botulism, tetanus, cranial cervical spinal cord lesions, brain injury, anesthetic complication, drug overdose, postcardiopulmonary resuscitation, respiratory muscle exhaustion caused by high work of breathing, diaphragmatic herniation, and chest wall trauma.

Mechanical ventilation can be used successfully to treat patients with various types of respiratory failure. However, it is an invasive procedure, requiring an artificial airway, heavy sedation, and intensive monitoring by trained professional caregivers. Potential complications such as ventilator-induced lung injury and nosocomial pneumonia may occur. There are also physiologic consequences secondary to the positive pressure applied to the lungs that may have a detrimental effect on cardiovascular, renal, hepatic and gastrointestinal functions.

CAUSES OF HYPOXEMIA

There are five main causes of hypoxemia: alveolar hypoventilation, ventilation-perfusion (V/Q) mismatch,

shunt, low inspired FiO_2 (high altitudes), and diffusion impairment. Clinically the first three causes are the most relevant.

Hypoventilation

Decreased alveolar minute ventilation *always* produces hypercarbia and hypoxia. The hypoxia can be abolished if the patient is breathing an increased FiO_2 ($\text{FiO}_2 > 0.21$), but the hypercarbia persists until an increase in minute ventilation occurs.

Ventilation/Perfusion Mismatching

This is the most common cause of hypoxemia. Alterations in V/Q ratios occur in diseased lung units through changes in airway resistance (asthma, bronchoconstriction), airway or vascular obstruction (airway secretions, alveolar/interstitial edema, and thromboemboli), and perfusion changes (pressure, permeability, cardiac output). Abnormalities in V/Q matching tend to have a more significant effect on the oxygen (O_2) content of the blood rather than on the carbon dioxide (CO_2) content. This effect can be attributed to the sigmoidal shape of the oxyhemoglobin-dissociation curve when compared to the linear relationship between CO_2 and hemoglobin saturation.

Shunt

Shunting occurs when blood flow continues through unventilated alveoli (or bypasses the lungs completely as in the case of an anatomic shunt such as a cardiovascular anomaly). This is the *only* cause of hypoxemia resistant to oxygen supplementation, but it is rarely present in a pure form (i.e., not accompanied by other causes of hypoxemia).

CAUSES OF HYPERCAPNIA

Hypercapnia is always associated with an inability to adequately remove CO_2 from the venous blood. This is usually because of a failure of the ventilatory pump (i.e., the bellows motion of the lungs to move air in and out). This may occur either because of an overload of the pump (increased cellular CO_2 production, airway obstruction, and exhaustion from the work of breathing) or the inability to pump (central nervous system [CNS] disease, hypoventilation, and respiratory muscle dysfunction).

Theoretically both V/Q mismatch and shunt should cause hypercapnia, but the respiratory centers detect the elevation and increase minute ventilation to maintain CO_2 levels. Thus only when the injury is sufficiently severe, further increases in minute ventilation cannot be accomplished, and the work of breathing exhausts the patient does hypoventilation occur and elevate CO_2 levels.

VENTILATOR SETTINGS

Modern critical care ventilators are complex with multiple settings to optimize the breath delivery to the patient. The first decision is determining whether control is based on delivered gas volume per breath (volume-cycled) or the

applied inspiratory pressure per breath (pressure-cycled). Volume-cycled ventilators deliver a predetermined tidal volume regardless of the airway pressure delivered volume creates. Pressure-cycled ventilators deliver a breath to a predetermined airway pressure; as a result tidal volumes may vary. Modern critical care ventilators are able to deliver both volume- and pressure-cycled ventilation. In patients with healthy lungs volume-cycled modes offer predictable minute ventilation without significant risk of creating ventilator-induced lung injury. In patients with lung injury limiting the inspiratory pressure (pressure-cycled ventilation) decreases the risk of damage to the diseased airways. The major disadvantage of this mode is the unpredictability of cycle-to-cycle tidal volumes because the volume of gas delivered is determined by the lung mechanics at any given moment in time.

The next decision is determining how much control the patient will exert over the breaths delivered by the ventilator. There are three types of patient breaths. *Controlled* breaths are delivered according to the respiratory rate and tidal volume settings of the ventilator. A controlled breath is delivered at a set time interval and ignores the patient's efforts to breathe. *Assisted* breaths are delivered according to the tidal volume settings of the ventilator, but the patient can, within some parameters, determine the rate of breath delivery. The patient is able to initiate an *assisted* breath; however, the ventilator then mechanically delivers the remainder of the breath to achieve the volume or pressure limits of tidal volume delivery. *Spontaneous* breaths can also occur in some ventilator modes. Spontaneous breaths occur when the patient is breathing faster than the rate settings of the ventilator in some modes (see following paragraphs). Traditionally the ventilator did not mechanically support spontaneous breaths, and the patient encountered high levels of resistance and dead space by having to breathe through an endotracheal tube and the ventilator circuit tubing. Modern ventilators frequently have several support options for spontaneous breaths designed to decrease the work of breathing associated with spontaneous breaths.

Two additional settings to consider in the initial ventilator setup include the *sensitivity* and the FiO_2 . The responsiveness of the ventilator to patient efforts to initiate breathing (assisted or spontaneous breaths) is determined by the sensitivity setting. It should be set to maximize patient comfort and minimize patient-ventilator asynchrony. The FiO_2 of breath delivery determines the concentration of oxygen in the breath delivery and should be set to the lowest concentration possible to allow adequate blood oxygen content and delivery.

The breath delivery mode of the ventilator should be chosen to achieve maximal patient-ventilator synchrony. The available modes on most ventilators include assist/control (A/C), synchronized intermittent mandatory ventilation (SIMV), and spontaneous (SPONT). In A/C mode no spontaneous breaths are allowed. In this mode the ventilator assists patient inspiratory efforts faster than the rate setting of the ventilator (assisted breaths). If the patient makes no inspiratory efforts, controlled breaths are delivered at the rate set by the ventilator. This mode tends to be used most commonly when patients are under general anesthesia or have a poor respiratory drive. Patients

capable of making significant inspiratory efforts are not likely to be comfortable in this mode of ventilation.

The *SMV* mode allows both mechanical and spontaneous breaths to be delivered according to patient demand. The type of breath delivered depends on the rate setting of the ventilator and the inspiratory efforts made by the patient. If the ventilator detects no patient effort, controlled breaths are delivered according to the rate setting. If the patient is making some efforts, the ventilator attempts to synchronize assisted breaths with patient effort as often as possible. If the patient is making inspiratory efforts above the ventilator rate settings, spontaneous breaths are permitted. This mode allows more comfort for the patient and is less likely to result in ventilator-patient asynchrony. Patients with high respiratory drive and vigorous inspiratory efforts may not find this mode comfortable, depending on how many mandatory machine-delivered (assisted/controlled) breaths are set.

In *SPONT* mode the ventilator delivers no mandatory mechanical breaths. All breaths are spontaneous. If the ventilator permits spontaneous breath support, the amount and type of support can be titrated to the patient's needs. This mode is typically used for patients in which the underlying condition has improved significantly and those that have vigorous and strong inspiratory efforts. This mode is frequently a preweaning mode.

The final setting to determine concerns *positive end-expiratory pressure* (PEEP) and how much will be applied. After a positive-pressure breath, the patient's lung is allowed to return to normal atmospheric pressure at the end of expiration. In injured lungs this results in cyclic opening and collapse of small airways and alveoli, which contributes to further lung damage and worsening gas exchange. Application of PEEP prevents the lung from returning to normal atmospheric pressure at the end of expiration. PEEP acts as an airway splint at the end of expiration to prevent further airway injury and can also result in improved oxygenation as a result of: (1) increase in the functional residual capacity, (2) alveolar recruitment, (3) improved V/Q matching, and (4) redistribution of the extravascular lung water.

A clinician responsible for ventilator care must be familiar with the settings, modes of ventilation offered, and additional options for tailoring breath delivery of the ventilator in use. Such knowledge optimizes breath delivery to the patient while decreasing the risk of ventilator injury.

VENTILATOR-INDUCED LUNG INJURY

In past decades our understanding of acute lung injury and the pulmonary response to ventilation has increased dramatically. Patients with lung injury have edema, bleeding, or inflammation within the alveolus and connecting airways. These substances inactivate surfactant and lead to alveolar collapse and atelectasis. In severe disease only a fraction of the lung may be ventilating and perfusing normally, thus dramatically decreasing effective gas exchange. Experimental trials using traditional mechanical ventilation strategies have documented many types of ventilator-induced lung injury in these settings. High mean airway pressures and use of tidal volumes that are

excessive to the amount of functional gas exchange tissue cause capillary fragmentation, tearing, and leakage of blood and plasma into the alveolus, setting the stage for further collapse and more functional loss. A second type of injury also occurs in marginal small airways and alveoli, which are partially collapsed. If the end-expiratory pressure is allowed to return to atmospheric pressure, these airways are repeatedly opened and closed, and a shear stress injury occurs to the airway/alveoli. Human clinical trials and experimental animal studies have demonstrated the increased production of proinflammatory cytokines in the lungs during these conditions. The increased production of cytokines may have a systemic effect, increasing the risk of multiple organ dysfunction in patients with ARDS.

A lung-protective strategy has been developed to lessen the ventilator-induced injury in lung-injured patients. This approach uses very low tidal volumes (4 to 6 ml/kg) and limits airway pressures (<35 cm of H₂O) to minimize pressure- and volume-induced injury and uses PEEP (8 to 14 cm of H₂O) to maintain marginal airways/alveoli open, prevent airway shear stress, and improve oxygenation. One cost of such lung protection is often hypoventilation. A lung-protective ventilation strategy permits mild-to-moderate hypercapnia (partial pressure of alveolar CO₂ [PaCO₂] of approximately 70 to 80 mm Hg) to occur.

VENTILATING THE NON-LUNG-INJURED PATIENT

When ventilating the patient that has not experienced lung injury, the following are the goals of therapy:

1. Restore respiratory function until resolution of the underlying problem occurs (i.e., neuromyopathy resolves or muscle strength returns).
2. Restore/maintain normal gas exchange. No lung pathology should exist; thus normal blood gas values should be achievable on or just above room air (21% oxygen).
3. Sedation should be titrated to prevent agitation associated with mechanical ventilation. Heart rate, blood pressure, oxygenation, and patient-ventilator synchrony (tolerance of endotracheal tube and ventilator breaths and general anxiety) should serve as guidelines of patient comfort.
4. If the duration of ventilation is expected to be longer than 24 hours, early consideration of a tracheostomy is appropriate (ideally within the first 12 hours).
5. Continuous monitoring of the electrocardiogram (ECG), blood pressure, urine output, end-tidal CO₂ (ETCO₂ using a capnograph), and oxygen saturation (SaO₂ using a pulse oximeter) should take place. Arterial blood gases should be measured twice daily and compared to noninvasive parameters to assess patient status and noninvasive monitoring efficacy. Deviations of ETCO₂ and SaO₂ out of normal ranges or worsening of clinical status also indicate a need for arterial blood gas analysis.

Initial recommended ventilator settings for these patients include the following:

Mode:	SIMV or A/C using volume-cycled breath delivery
Tidal volume:	10 to 12 ml/kg
Rate:	10 to 15 beats/min
FiO ₂ :	0.21 to 0.30
PEEP:	1 to 5 cm of H ₂ O
Sensitivity:	2 to 5 cm H ₂ O or 1 to 2 L/min (adjust for patient-ventilator synchrony)

Ventilation at these settings should continue for 20 minutes and then be assessed with blood gas analysis. Initial FiO₂ settings can be higher until the patient is stable but should then be decreased to the lowest value that permits adequate oxygenation. Fine tuning can then take place unless the patient appears distressed or bedside monitors indicate that earlier changes are required. Alarms should be adjusted to maintain reasonably safe zones but not so tight that frequent violation occurs (unless the patient is currently functioning in the edge of a safe zone).

VENTILATING THE LUNG-INJURED PATIENT

When ventilating the patient with pulmonary injury, the goals of therapy include the following:

1. Support ventilation and oxygenation until sufficient lung healing or respiratory muscle strength returns to allow weaning.
2. Because of lung injury and impaired gas exchange, blood gas values should not be expected to be ideal. Oxygen therapy should be adjusted to maintain arterial partial oxygen pressure at 60 to 80 mm Hg using the lowest possible concentration of oxygen to decrease the likelihood of oxygen toxicity. Levels above 60% for greater than 24 to 36 hours are thought to contribute to such toxicity.
3. PEEP should be used to recruit collapsed airways and increase compliance and oxygenation.
4. Patients with severe lung injury have decreased lung volumes available for gas exchange; thus ventilation with normal tidal volumes can induce volume and pressure injury to the healthy lung because of overdistention. Use of small tidal volumes, pressure-cycled ventilation and close trending of both peak and mean airway pressure in conjunction with PEEP therapy help to prevent further ventilator-induced lung injury. Use of such a lung-protective strategy may result in some CO₂ retention. Hypercapnia at mild-to-moderate levels (70 to 80 mm Hg) does not appear to have any detrimental effects on the patient.
5. Sedation should be titrated to the lowest level to prevent agitation associated with mechanical ventilation. Heart rate, blood pressure, oxygenation, and patient-ventilator synchrony (tolerance of endotracheal tube and ventilator breaths and general anxiety) should serve as guidelines of patient comfort. Lung-injured patients with permissive hypercapnia have strong respiratory efforts in response to CO₂ elevations and require deep sedation or anesthesia to achieve acceptable patient-ventilator synchrony.

6. If the duration of ventilation is expected to be longer than 24 hours, early consideration should be given to tracheostomy.
7. Continuous monitoring of ETCO_2 , SaO_2 , ECG, blood pressure, and urine output should take place. The accuracy of capnography and pulse oximetry is likely to be significantly less accurate in lung-injured, severely hypoxemic patients; thus a greater reliance should be placed on frequent arterial blood gas samples. Capnography and pulse oximetry can still be used for trending and can alert the caregiver of potential problems.

Initial ventilator settings for the lung-injured patient include the following:

Mode:	SIMV pressure-cycled breaths with spontaneous breath support
Tidal volume:	Dependent on pressure setting. Aim for lowest possible pressure setting that achieves tidal volumes of 4 to 6 ml/kg. Do not exceed mean airway pressures of 35 cm of H_2O if possible.
Rate:	18 to 30 beats/min
FiO_2 :	0.30 to 1 (use the lowest possible fraction)
PEEP:	8 to 15 cm of H_2O
Sensitivity:	2 to 5 cm of H_2O or 1 to 2 L/minute (adjust for patient-ventilator synchrony)

Ventilation at these settings should continue for 20 minutes and should then be assessed with blood gas analysis. Fine-tuning can then proceed unless the patient appears distressed or bedside monitors indicate that earlier changes are required. Alarms should be adjusted to maintain reasonably safe zones but not so tight that frequent violation occurs (unless patient is currently functioning in the edge of a safe zone).

CARDIOVASCULAR IMPLICATIONS OF POSITIVE-PRESSURE VENTILATION

The interactions of positive-pressure ventilation and the cardiovascular system are complex and depend to a large extent on the mode of ventilation being used. Elevated intrathoracic pressure from positive-pressure ventilation can impede ventricular filling and decrease preload and cardiac output. Conversely high pressures can decrease afterload from elevation of transmural pressure on the ventricle, increasing cardiac output. Thus the end result of an increased or decreased cardiac output depends to a large extent on volume status of the patient, underlying myocardial function, and mean intrathoracic pressures produced by mechanical ventilation. Patients with impaired left ventricular function may have an increase in cardiac output, but patients with hypovolemia or in which higher levels of PEEP are necessary may experience a decline in cardiac output. Ultimately the goal of mechanical ventilation should be to improve oxygen delivery to the tissues, not to increase the oxygen content of the arterial blood; thus maintaining cardiac output is extremely important. At some point the cost of ventilation (in declining cardiac output and resultant decreasing oxygen delivery) outweighs the benefit of increasing arterial oxygen content.

Small decreases in cardiac output likely result in activation of the renin-angiotensin-aldosterone-vasopressin system, with retention of sodium and water. Thus mechanically ventilated patients may experience decreased urine output because of these effects. Peripheral edema also may occur.

PATIENT-VENTILATOR ASYNCHRONY

Patient agitation and distress can result in counterproductive fighting against the ventilator. The most common causes of this problem are incorrect ventilator setup for the patient's respiratory drive or psychologic comfort, an acute change in the clinical status of the patient, obstruction of the airway, development of pneumothorax, or malfunction of the ventilator. The correct response to patient-ventilator asynchrony should involve the following steps:

1. Auscultate both lung fields for breath sounds and observe chest wall motion for synchrony.
2. Assess depth of sedation (palpebral reflex, jaw tone).
3. Disconnect the patient and hand ventilate to assess compliance.
4. Suction the airway.
5. Consider reintubation of the patient.
6. Perform an arterial blood gas analysis to determine the patient's status.

If none of these activities reveal the problem, the patient should be repositioned to a more comfortable position, or if this is not possible the plane of sedation adjusted. As a final step consideration of a different mode of ventilation may be necessary (e.g., changing from A/C to SIMV may provide more patient comfort).

MAINTAINING SEDATION/ANALGESIA DURING MECHANICAL VENTILATION

Several combinations of drugs can maintain patient comfort during mechanical ventilation. Generally patients without lung injury can be maintained comfortably using combined continuous infusions of opioids and benzodiazepines. Morphine (0.1 to 0.3 mg/kg/hour), hydromorphone (0.015 to 0.03 mg/kg/hour), or fentanyl (1 to 5 mcg/kg/hour) and diazepam (0.1 to 0.5 mg/kg/hour) following loading doses are reliably safe and inexpensive and both drug classes can be reversed easily when weaning is attempted.

Lung-injured patients typically are more difficult to control because of high ventilatory drive from hypercarbia or hypoxemia. The use of lung-protective ventilation strategies may also increase the likelihood of hypercapnia, auto-PEEP at high respiratory rates (RR), decreased alveolar minute volume, and ventilator-patient asynchrony. To overcome these issues, more potent CNS-depressant drugs must be administered. Historically pentobarbital was the most commonly used agent for this purpose and was administered as a continuous infusion (1 to 5 mg/kg/hour) after induction of anesthesia at 5 to 15 mg/kg. However, pentobarbital appears to have immunosuppressive effects when used for several days

and is no longer the first choice in maintaining sedation (particularly in infectious pneumonia). Combinations of medications seem to be a better choice. The combinations that are potentially beneficial are propofol with a benzodiazepine or opioid infusion (fentanyl, hydromorphone, or morphine) or ketamine (100 to 300 mcg/kg/minute) in combination with an opioid and benzodiazepine infusion. Propofol infusions are also helpful during weaning from the ventilator because of its superior ability to achieve rapid titration (25 to 600 mcg/kg/minute). In severe situations when these regimens are unable to control patient ventilator asynchrony, the addition of a neuromuscular blocking agent should be used. Continuous infusion of atracurium is associated with the least side effects but should not be used for longer than 12 to 24 hours because of the incidence of severe myopathy/myoparesis syndromes (0.3 to 0.5 mg/kg/hour after a loading dose of 0.2 to 0.4 mg/kg). Atracurium is metabolized by Hoffman elimination; thus reduced dosages are necessary in acidemic or hypothermic patients. It is *essential* to provide analgesia and sedation in addition to neuromuscular blockade. Monitoring of the blockade and adjustment of dosage should be based on neuromuscular stimulation (train of four). Neuromuscular blockade must be reversed completely before weaning attempts.

CARE AND COMFORT OF THE MECHANICALLY VENTILATED PATIENT

Pulmonary Toilet

Airway obstruction caused by excessive buildup of secretions in the airway results in inefficient ventilation and can be caused by loss of the cough reflex, abrogation of the mucociliary clearance apparatus, and bronchorrhea (in lung injury). However, frequent suctioning can inflict further injury to the trachea and the mucociliary clearance. Therefore suctioning of the airway should be performed only as needed. Sterile in-line suction catheters are commercially available for this purpose. *Strict aseptic techniques should be used at all times.* Advancing the suction catheter only to the end of the tube in place, applying suction only on the withdrawal phase, and withdrawing slowly so that only one cycle of suctioning gets most of the secretions aids in reducing iatrogenic airway damage. Secretions can be collected for culture and sensitivity from the suction catheter or via separate tracheal wash samples. The patient should be preoxygenated and hand ventilated during suctioning if required.

Humidification of the airway, gases, and secretions is vital to successful treatment. Use of a heat and moisture exchanger should be sufficient to accomplish this goal. Alternatively humidification and temperature adjustment of the inspired gas can be accomplished with specifically designed humidification devices. Medications (β -agonists, anticholinergics, and corticosteroids) can be delivered by metered-dose inhalers through the ventilator circuit if necessary.

Other measures are important. Corneal ulceration and conjunctivitis are also very common. Sterile eye lubricants

should be applied when necessary to prevent drying. A urinary catheter should be placed to maintain patient comfort. Diligent assessment of urinalysis for signs of bacterial cystitis and culture and sensitivity should be performed on a regular basis. Regular position shifts, massage, and physical therapy are helpful to maintain patient comfort. Adequate padding and absorbent bedding that is kept clean and dry is a requirement for these patients. Use of enteral feeding methods is desirable to maintain good gut barrier health, prevent translocation of bacteria, and prevent colonization of the flora with more pathogenic microbial strains.

Ventilator-Associated Pneumonia

Ventilator-associated pneumonia (VAP) is a possible sequel to mechanical ventilation and increases the risk of mortality by 2 to 10 times in humans. Mechanically ventilated patients are at an increased risk of developing a nosocomial pneumonia for several reasons such as altered level of consciousness, decreased gag reflex, alteration in the normal host respiratory tract defenses, delayed gastric clearance, ileus, previous antimicrobial usage, days of hospitalization, and aspiration of oropharyngeal secretions. Endotracheal intubation increases the risk of this complication in humans by 6 to 21 times, and every day of ventilation raises this risk by 1% to 3%. The pathogenesis of VAP is associated with the colonization of the aerodigestive tract with pathogenic microbes early in the course of hospitalization and aspiration of the contaminated secretions. The patient may also become infected by direct inoculation from intubation or secondary to caregivers who act as fomites for resistant microbes in the intensive care unit (ICU) environment. Strict attention to aseptic technique helps to prevent this complication. Implementation of strict hand-washing policies, barrier protective clothing, and policies directing traffic patterns within the ICU unit are considered helpful preventive measures. However, to prevent this complication a multifaceted approach is required. Excellent oral care, enteric feedings, titration of sedation to the lowest levels to ensure patient comfort, use of ventilator modes that aid in patient-ventilator synchrony, and responsible stewardship of antimicrobial drugs may all contribute to a decreased incidence of VAP. Early recognition of this complication is important, along with prompt initiation (ideally less than 12 hours after clinical diagnosis) of appropriate broad-spectrum antibiotics with culture and sensitivity testing to confirm and narrow the choice of antimicrobials.

Oral lesions are also very common in ventilator-dependent patients because of pressure necrosis from the endotracheal tube and monitoring devices. Cleansing of the oral cavity four to six times daily with dilute chlorhexidine solution (include the oropharynx and subglottal regions) and use of glycerin-soaked gauze pads on pressure points help maintain a more desirable oral bacterial flora. A sterile endotracheal tube should be used initially, and this tube should not be replaced unless viscous secretions are occluding the lumen.

WEANING FROM THE VENTILATOR

Weaning from mechanical ventilation can be a difficult process in some patients. Ideally a gradual reduction in the amount of ventilatory support with a concomitant increase in the participation of the patient in the work of breathing should take place. No objective measurement determines weaning success in humans, and no standardized methods have been described in veterinary medicine. One recommended technique is to use daily trials of spontaneous breathing. Most patients who fail the weaning process rapidly develop an increased frequency and decreased tidal volume of breathing. Patients who fail a weaning process should be continued on the latest level of support with further decreases of ventilatory assistance at prescribed intervals. Daily trials of spontaneous breathing should continue until weaning is successful. During the weaning process sedation with agents that are rapidly reversible or with short half-lives is preferred.

CHAPTER 139

Rhinitis in the Dog

NED F. KUEHN, *Southfield, Michigan*

Sneezing and nasal discharge usually are associated with diseases of the nose, paranasal sinuses, and nasopharynx. Sneezing frequently precedes the onset of notable nasal discharge. The severity and frequency of sneezing may diminish over time, whereas the nasal discharge frequently worsens in severity and changes in character. Therefore dogs with chronic rhinitis are frequently presented with chronic nasal discharge rather than persistent sneezing. The nature of sneezing may aid in localizing the region of the problem. Expiratory sneezing typically is associated with sinus or intranasal disease. Reverse or inspiratory sneezing (aspiration reflex) is a normal response to mechanical irritation of the dorsal nasopharyngeal mucosa. The presence of reverse sneezing is usually correlated with caudal nasal, nasopharyngeal, or sinus disease. Some dogs may have posterior rather than anterior nasal discharge, and the only indication for primary nasal disease may be obstructive nasal breathing.

The causes for nasal discharge in the dog are included in Box 139-1. The principle diseases associated with chronic rhinitis are sinonasal neoplasia, idiopathic lymphoplasmacytic rhinitis, and fungal rhinitis (Lefebvre et al., 2005). Nasal discharge is not limited to primary nasal disease but also may occur with systemic and extranasal disorders. Very often extranasal disorders have systemic signs (e.g., depression, pyrexia, hemorrhage) and a history of acute onset, whereas primary nasal disorders have a more chronic duration. Important extranasal disorders that may present with nasal discharge include coagulopathies, vasculitis, hypertension, hyperviscosity syndrome, and pneumonia.

The character and type of nasal discharge may be helpful in developing a list of potential causes, but they are not characteristic for specific diseases. Unilateral discharge is often associated with neoplasia, fungal and foreign body rhinitis, and dental disease. Bilateral discharge is typical of systemic disorders, advanced neoplasia or fungal rhinitis,

Box 139-1

Differential Diagnosis for Nasal Discharge**Nasal and Paranasal Sinus Disorders**

- Allergic rhinitis
- Bacterial rhinitis (*Bordetella bronchiseptica*, *Pasteurella multocida*)
- Ciliary dyskinesia
- Dental disease
- Foreign body
- Fungal rhinitis (*Aspergillus fumigatus*, *Penicillium* spp., *Rhinosporidium seeberi*, *Cryptococcus neoformans*)
- Hyperplastic rhinitis (Irish wolfhounds)
- Idiopathic lymphoplasmacytic rhinitis
- Neoplasia
- Nasal parasites (*Pneumonyssus caninum*, *Eucoleus* [*Capillaria*] *boehmi*)
- Oronasal fistula
- Palatine defects
- Trauma

Viral infection or Extranasal Disorders

- Coagulopathies
- Cricopharyngeal disease
- Environmental agents (dusts, smoke)
- Esophageal stricture
- Hypertension
- Hyperviscosity syndrome
- Immunoglobulin A immunodeficiency
- Megaesophagus
- Oropharyngeal diseases
- Pneumonia
- Polycythemia
- Thrombocytopenia
- Vasculitis
- Vomiting

idiopathic lymphoplasmacytic rhinitis, and allergic rhinitis. However, it also is possible for systemic disorders and idiopathic lymphoplasmacytic rhinitis to present with only unilateral nasal discharge. Serous nasal discharge may be seen initially with a variety of nasal disease but often becomes mucopurulent as disease progresses and secondary bacterial invasion occurs. Mucopurulent nasal discharge is most common and indicates bacterial infection *secondary* to an underlying disorder that has damaged the nasal mucosa with resultant bacterial invasion. Primary bacterial infection is an exceedingly rare cause of rhinitis in dogs. Mucopurulent and serous discharges may be blood tinged as a result of mucosal erosion. Epistaxis usually results from an underlying nasal disorder causing erosion of a major blood vessel but also may be seen with systemic disorders such as coagulopathies, hypertension, vasculitis, or hyperviscosity syndrome.

DIAGNOSIS

Clinical history and physical examination findings generally offer an indication for primary nasal disease as opposed to systemic or extranasal disease. Routine laboratory tests (complete blood count, serum chemistries, urinalysis), coagulation profile, blood pressure, and thoracic

radiographs are important to rule out most of the systemic or extranasal causes for nasal discharge. Cytologic evaluation of nasal discharge is rarely helpful other than possibly for identification of *Eucoleus* [*Capillaria*] *boehmi* parasitic ova. Bacterial and fungal cultures of nasal discharge are not recommended because they are nonspecific and simply represent resident bacteria and fungi. Serologic tests for aspergillosis and penicilliosis should be delayed because some normal dogs and some dogs with nasal neoplasia have positive results (Sharp, 1998). Empiric antimicrobial treatment is not advised and merely delays definitive diagnosis unless chronic *Bordetella bronchiseptica* or *Pasteurella multocida* rhinitis (both very rare) or pneumonia is present. Mucopurulent nasal discharge is almost always a result of secondary bacterial rhinitis caused by an underlying primary nasal disease.

Anesthesia is required for further evaluation of most dogs with rhinitis. A thorough oral examination with inspection of the hard palate, oropharynx, and dental structures should be performed. A periodontal probe should be used to inspect the gingival sulci of maxillary teeth. Oronasal fistulae are often associated with the maxillary third incisors, first and second premolars, and mesial root of the third premolar.

Diagnostic imaging studies are performed with the patient under anesthesia. Imaging studies often are essential in most dogs with chronic rhinitis to help achieve a diagnosis. It is critical that imaging studies be completed *before* rhinoscopy or collection of intranasal samples so that secondary hemorrhage does not obscure subtle lesions or affect the quality of diagnostic images. If dental disease is suspected, dental films are recommended to evaluate the questionable teeth and surrounding structures. Radiographic images of the nose and sinuses may provide some insight but often do not reveal a specific cause for the nasal disease. Radiographs often lack sufficient resolution to identify or localize early nasal disease. Computed tomography (CT) is vastly superior to plain radiographs of the nasal cavity (Lefebvre et al., 2005). Nasal CT provides a thorough assessment of the nasal cavities and paranasal sinuses and provides superior insight to the nature and extent of disease (Figs. 139-1 to 139-5). Nasal CT often can differentiate neoplasia, fungal rhinitis, and inflammatory rhinitis. Contrast-enhanced CT images are useful to distinguish between vascularized soft tissue and mucus accumulation. Because nasal CT clearly demonstrates the location and extent of nasal disease, it is often used to help guide postimaging rhinoscopic and biopsy procedures and delineate nasal tumors for radiation therapy. If routine diagnostics do not provide a cause for rhinitis, referral to an institution providing CT imaging is advised. Although magnetic resonance imaging (MRI) is often considered superior to CT for delineation of tumor borders, a recent study failed to document an advantage of MRI over CT in detecting intracalvarial changes in dogs with nasal neoplasia (Dhaliwal et al., 2004) CT images regularly provide valuable clinical information without the need for MRI.

Rhinoscopy should only be performed after all imaging studies are completed with the patient under anesthesia. The nasopharynx is examined before the nasal cavity because, if hemorrhage is induced by examination of the

Fig. 139-1 Computed tomography scan from the middle region of the nasal cavity in a dog with nasal aspergillosis involving the right nasal cavity. The right nasal cavity is devoid of turbinate structures (*arrow*) with scattered regions of soft-tissue densities (mucopus) present. The left nasal cavity has normal turbinate structures.

Fig. 139-2 Computed tomography scan within the midregion of the nose from a dog with lymphoplasmacytic rhinitis. Moderate turbinate destruction with scattered soft-tissue densities (mucopus) is present within both sides of the nasal cavity.

nasal cavities, blood frequently pools in the nasopharynx and obscures visualization of this area. Retroflex nasopharyngoscopy is performed by turning a small flexible scope 180 degrees around the caudal margin of the soft palate to evaluate the caudal nares, dorsal soft palate, and nasopharynx. Tumors or foreign bodies lodged within the caudal nares or within the nasopharynx are occasional causes for rhinitis in dogs. Anterior rhinoscopy may be limited by the size of the nasal cavity compared to the size of the scope, lesion location, and impeded visualization of intranasal structures by mucus or hemorrhage. The convoluted nature of the nasal passages does not allow for evaluation of the entire nasal cavity; thus foreign bodies and neoplastic masses may be overlooked. The mucosa should be evaluated for color, vascularity, friability, edema, and presence of parasites or fungal plaques. Artifacts associated with close illumination of the mucosa should be

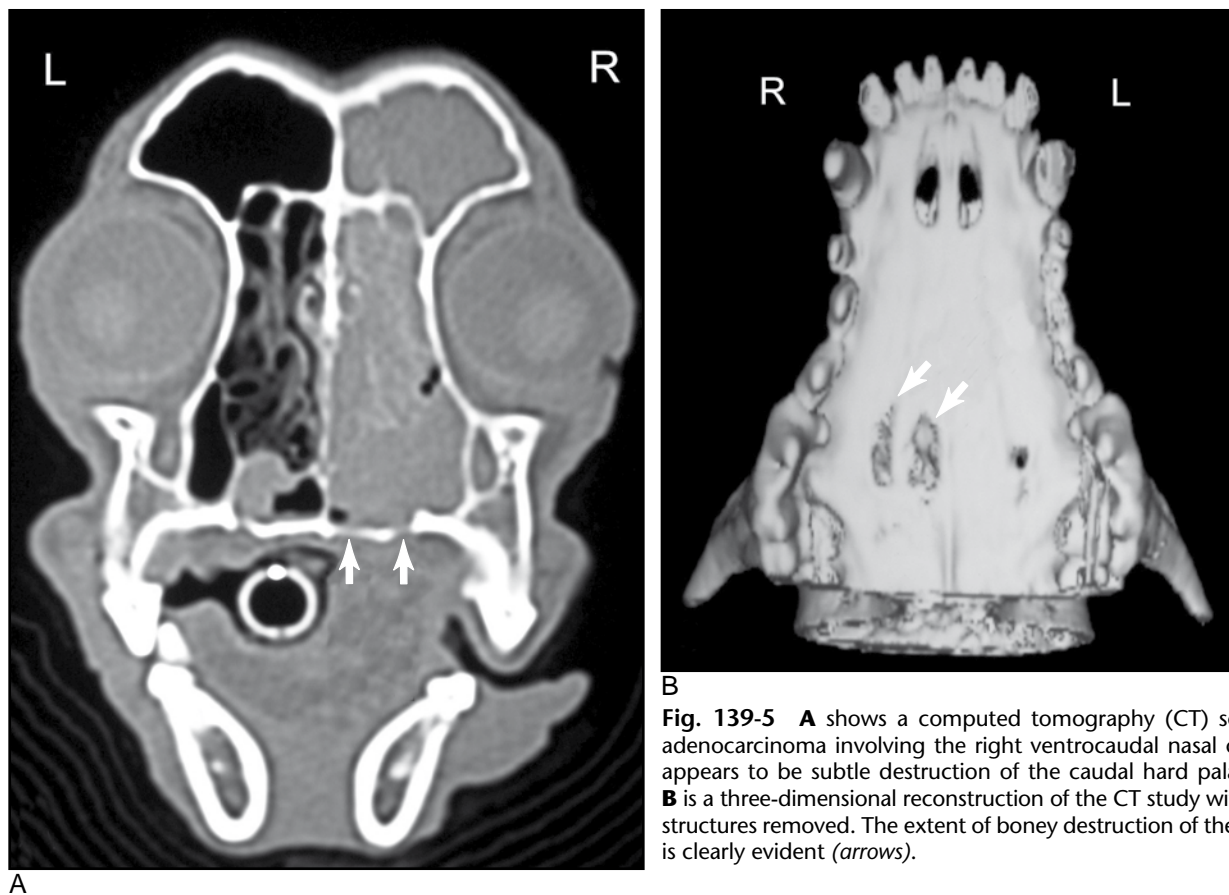

Fig. 139-3 Computed tomography scan within the caudal region of the nose from a dog with adenocarcinoma. Destruction of the dorsal nasal septum (*straight arrow*) and extensive destruction of the bones surrounding the left frontal sinus (*curved arrow*) are present. Facial deformity was present and can be appreciated by the soft-tissue swelling above the left frontal sinus.

appreciated. The nasal passages should be evaluated for obstruction by tissue masses, foreign bodies, or secretions. A loss of normal nasal turbinates would indicate the presence of a destructive rhinitis secondary to fungal infection or severe idiopathic lymphoplasmacytic rhinitis. Rhinoscopy is especially helpful to aid in the diagnosis of fungal rhinitis and rostrally positioned nasal foreign bodies. Fungal rhinitis often is associated with widespread turbinate destruction, and rhinoscopy may reveal a cavernous nasal cavity with off-white-to grey-fungal plaques scattered across the surface of the nasal mucosa.

Procurement of nasal specimens and biopsies of nasal tissue should be performed only after imaging and visual examinations are completed and while the patient is still under anesthesia. Cytology of nasal secretions is rarely useful, but brush cytology from masses or fungal plaques may be useful. Stained direct smears of nasal tissue specimens also can be helpful for identifying fungal organisms. Tissue from lesions visualized during rhinoscopy may be obtained by direct biopsy with forceps passed either adjacent to or through the endoscope. Rhinoscopy-directed biopsies from masses identified within the nose can be limited by the size of tissue samples obtained and inflammation surrounding the mass. Lymphoplasmacytic inflammation often is present with intranasal neoplasms, whereas idiopathic lymphoplasmacytic rhinitis is not associated with mass lesions in the nose. I prefer to use nasal CT images to guide instrumentation for procurement of biopsy samples. Depending on the size of the nose, either small clam-shell or colonic biopsy forceps are advanced to the site of disease as identified from CT images, and multiple biopsies are then obtained. During the biopsy procedure it is recommended that the dog be in sternal recumbency with the rostral end of the nose directed downward to facilitate drainage of hemorrhage away from the nasopharynx and oropharynx. Following

Fig. 139-4 Computed tomography scans from the midregion (**A**) and further caudal region (**B**) of the nose in a dog with adenocarcinoma. The nasal septum is destroyed rostrally (arrow **A**) by the neoplasm but intact caudally (arrow **B**).

B

Fig. 139-5 **A** shows a computed tomography (CT) scan of nasal adenocarcinoma involving the right ventrocaudal nasal cavity. There appears to be subtle destruction of the caudal hard palate (arrows). **B** is a three-dimensional reconstruction of the CT study with soft-tissue structures removed. The extent of bony destruction of the hard palate is clearly evident (arrows).

biopsy, the tip of the nose remains positioned downward, and the oropharynx and cranial esophagus are suctioned to remove blood clots. Nasal lavage may be required to dislodge foreign material identified or suspected to be present within the nose. The rostral aspect of the nose should be directed downward while copious amounts of

saline are flushed vigorously through the nostrils. The endotracheal tube cuff should be inflated to prevent aspiration pneumonia. Some clinicians surround the glottis with surgical sponges or gauze.

Tissue samples are not submitted routinely for bacterial or fungal culture unless osteomyelitis is present. Nasal

fungal and bacterial tissue cultures must be interpreted cautiously because fungal and bacterial isolates may be a consequence of nasal passage colonization rather than the cause of a given disease process. Primary bacterial rhinitis is exceedingly rare in the dog, and almost all bacterial infections develop secondary to underlying primary nasal disease. A heavy growth of even one or two bacterial isolates may merely be indicative of bacterial colonization; however, pure isolates of *B. bronchiseptica* and possibly *P. multocida* may be significant if the clinical history is supportive. Normal dogs and dogs with nasal neoplasia or foreign bodies may have positive fungal cultures for *Aspergillus* spp. A positive fungal culture should be supported by diagnostic imaging, cytologic, rhinoscopic, or histologic evidence of infection (Mathews, 2004). If tissue cultures are submitted, these must be interpreted carefully in light of histopathologic and other diagnostic information.

TREATMENT OF COMMON CAUSES OF RHINITIS

Geographic locality plays a role; but, excluding nasal foreign bodies (Aronson, 2004) and dental disease, the most common causes for chronic rhinitis in dogs are neoplasia, idiopathic chronic (lymphoplasmacytic) rhinitis, and fungal rhinitis. Parasitic rhinitis is uncommon. The treatment for nasal mites (*Pneumonyssus caninum*) is ivermectin 0.2mg/kg orally, with the dose repeated in 2 to 3 weeks. The treatment for nasal nematodes (*E. [Capillaria] boehmi*) is not clearly defined, although ivermectin 0.2mg/kg orally once reportedly has been effective. Allergic rhinitis is often mild; but, if severe, antihistamines such as diphenhydramine, chlorpheniramine, or trimeprazine-prednisone (Temaril-P, Pfizer Animal Health) may be prescribed to control symptomatology. In the rare situation of bacterial rhinitis caused by *B. bronchiseptica*, doxycycline 5 to 10mg/kg every 12 hours orally for 2 weeks may be effective.

Fungal Rhinitis

Fungal rhinitis is a relatively common cause of chronic rhinitis in the dog in various geographic regions throughout the world. *Aspergillus fumigatus* is the most common cause of fungal rhinitis in dogs, but occasionally *Penicillium* spp., *Rhinosporidium seeberi*, and very rarely *Cryptococcus neoformans* may cause disease in dogs. *R. seeberi* is associated with the growth of a granulomatous mass within the rostral nasal cavity. Cytology of tissue from these granulomatous masses is often diagnostic. Treatment for rhinosporidiosis is best accomplished by aggressive surgical resection of the granulomatous mass.

Nasal aspergillosis is most commonly seen in young to middle-aged dolichocephalic dogs, with German shepherd and rottweiler breeds reported to be predisposed. Affected dogs present with copious unilateral or bilateral mucopurulent nasal discharge. Sneezing is common and may be accompanied by mild-to-severe epistaxis. Facial pain and depigmentation and ulceration of the nasal planum may be present. In contrast to nasal neoplasia, facial distortion is unusual in all but advanced cases of fungal rhinitis. Nasal CT (see Fig. 139-1) along with rhinoscopy is noteworthy for the presence of dramatic turbinate loss within

the nasal cavity (Saunders, 2004). Sinus involvement may be present. Invasion throughout the maxillary or palatine bones with extension into surrounding soft-tissue structures is seen occasionally. Nasal CT scan is preferred over radiographs so that the integrity of the cribriform plate can be evaluated before local antifungal therapy. A non-invasive form of nasal aspergillosis infrequently occurs in the dog and is characterized by compact masses of mycelia ("fungal balls") filling larger airtspaces or frontal sinuses.

Diagnosis of nasal aspergillosis is confirmed by visualization of fungal plaques on nasal mucosa and demonstration of branching septate hyphae on cytologic or histologic samples from affected regions within the nose. Serologic tests positive for aspergillosis also support the diagnosis, although negative results may occur even with extensive disease. Occasionally special staining methods for fungi may be useful for identifying fungal elements in tissue biopsy samples. Cultures of nasal discharge may be misleading in that 30% to 40% of cultures from normal dogs and those with nasal neoplasia can yield *Aspergillus* or *Penicillium* spp. Despite properly obtained samples some cases fail to demonstrate fungal organisms. Repeated sampling or a trial of antifungal drugs may well be indicated in dogs with a high index of suspicion for nasal aspergillosis.

The prognosis for treatment of nasal aspergillosis is fair to good, but relapses are possible necessitating retreatment (Schochet and Lappin, 2005). Treatment of nasal aspergillosis is best approached with topical infusion of either clotrimazole or enilconazole provided that the cribriform plate is intact. Topical therapy is more effective than orally administered antifungal agents. Clotrimazole (Lotrimin solution, Schering Plough Corp.) is available over the counter as a 1% solution, and enilconazole (Clinifarm-EC, Sterwin Labs, Inc.) is provided as 13.8% concentrate, which is diluted to a 1%, 2%, or 5% solution before instillation in the nasal cavity. Topical therapy with either drug alone is not effective in dogs in which the organism has invaded soft-tissue structures adjacent to the nose. In these cases it is recommended that topical therapy be combined with systemic antifungal agents. Rhinotomy and turbinectomy before topical treatment or oral antifungal therapy are often detrimental and not recommended.

The topical application of enilconazole through surgically placed catheters into the frontal sinuses and nasal chambers has a success rate as high as 90%. Catheters are implanted surgically into both nasal chambers and frontal sinuses via trephine holes in the sinuses. Enilconazole is flushed through the catheters twice daily at a dosage of 10mg/kg for a total of 7 to 10 days. Unfortunately this procedure is quite distressing to most patients. Complications include premature removal of the catheters, subcutaneous emphysema, inappetence, and ptialism. Some patients may become aggressive and intolerant of the procedure, necessitating premature abandonment of therapy. Because of these serious and frequent side effects, topical therapy with clotrimazole has become the treatment of choice. Clotrimazole is applied as a soak, with the solution maintained in the nasal cavities for 1 hour with the patient under anesthesia (Bonagura, 1995, 2000). A total volume of 60ml of a 1% solution of clotrimazole is infused slowly through catheters placed into the right and left nares.

A nasopharyngeal Foley catheter and sponges placed in the caudal pharyngeal region are positioned before the procedure to minimize leakage of the infusate caudally, and the external nares are also obstructed with Foley catheters. The head is rotated every 15 minutes to ensure contact with all nasal surfaces. As many as 90% of patients may be cured with a single procedure, although some dogs require a second procedure 3 weeks later. Side effects of clotrimazole therapy include severe pharyngitis and pharyngeal edema.

Recently another approach with excellent success rate, shorter treatment time, and low patient morbidity has been reported using a combination of clotrimazole irrigation and depot therapy (Sissener et al., 2006). Frontal sinus trephination is followed by a short, 5-minute flushing of 1% topical clotrimazole solution followed by a 1% clotrimazole cream instilled as a depot agent into the frontal sinuses. The procedure includes a number of steps. The anesthetized dog is positioned in sternal recumbency with the pharynx packed with cotton gauze to prevent aspiration of fluid debris, and the head is tilted downward to allow fluid from the nasal sinuses to drain rostrally. The frontal bone is trephined to permit passage of a 10 Fr-gauge Jacques urethral catheter into each sinus. The sinuses are first irrigated with 500ml of warm saline over 5 minutes to establish appropriate catheter placement and patency of the nasofrontal ostium (which communicates the frontal sinus with the nasal cavity). The sinuses are then irrigated with 1% clotrimazole solution. For dogs weighing more than 10kg, a total of 500mg is used (25ml per side). Clotrimazole 1% cream is then introduced into the frontal sinuses. For dogs larger than 10kg a total of 40g (20g per side) is used, and for dogs weighing less than 10kg a total of 20g (10g per side) is applied. The catheters are then removed, the skin incisions are closed, and excess fluid is allowed to drain from the sinuses before the pharyngeal gauze is removed. With this treatment protocol, 86% of dogs with nasal aspergillosis or penicilliosis established a cure from infection. I suspect that cure rate might be greater if débridement and removal of diseased nasal turbinates through the rostral nares were to precede treatment using the combination of clotrimazole irrigation depot therapy.

Oral antifungal agents have relatively poor efficacy against *Aspergillus* infection but are recommended if imaging demonstrates that the cribriform plate is penetrated. Oral antifungal agents are used in combination with topical agents if invasion of local bone and soft-tissue structures is present. The newer azole derivatives offer the best results. Side effects of the azole antifungal agents include anorexia, vomiting, lethargy, elevated blood urea nitrogen, skin ulcerations, fever, and hepatotoxicity. Itraconazole (Sporanox, Janssen) is recommended because of its low toxicity. Itraconazole 5 mg/kg every 12 hours orally given for 3 to 6 months may cure up to 60% to 70% of dogs with aspergillosis, although some studies have shown marginal effects of the drug on this disease. Terbinafine (Lamisil, Novartis) is another option; it is well tolerated. Terbinafine 5 to 10mg/kg every 12 hours orally appears to have similar efficacy to itraconazole when given for 3 to 6 months. Fluconazole (Diflucan, Pfizer) is another alternative with a cure rate up to 60% when given at a dose of 2.5 to 5 mg/kg every 12 hours orally for 3 to 6 months. Voriconazole (Vfend, Pfizer) is a new-generation broad-spectrum antifungal agent that

shows activity against a wide range of yeasts and filamentous fungi. Voriconazole demonstrates both fungicidal and fungistatic activities in vitro against *Aspergillus* spp. superior to that of fluconazole. Voriconazole may prove to be an effective antifungal drug for treatment; however, clinical experience with this drug is limited in veterinary medicine. Initial clinical experience in dogs suggests an oral dose of 5 mg/kg every 12 hours for voriconazole.

Idiopathic Lymphoplasmacytic (Chronic) Rhinitis

Idiopathic lymphoplasmacytic rhinitis is a relatively common cause of chronic nasal disease in the dog. The definitive etiology of lymphoplasmacytic rhinitis remains undetermined; however, it is likely a stereotyped chronic inflammatory response to multiple precipitating factors (Windsor, 2004). Inhaled aeroallergens and irritants probably play a primary role in development of this disease. Hypersensitivity to native commensal fungal organisms within the nose also may play a role in some patients. Young to middle-aged dolichocephalic and mesaticephalic large-breed dogs and dachshunds typically are affected. Chronic unilateral-to-bilateral mucoid-to-mucopurulent nasal discharge is often present, although some dogs may have mucohemorrhagic discharge or epistaxis. Obstruction to airflow through the nose may result from excessive mucus within nasal passages and turbinate mucosal edema. Since lymphoplasmacytic inflammation may be present with nasal neoplasia, fungal rhinitis, or foreign body rhinitis, it is imperative that these diseases be thoroughly excluded before a diagnosis of idiopathic lymphoplasmacytic (chronic) rhinitis is entertained.

Nasal radiography is not sufficient to differentiate chronic inflammatory rhinitis from neoplasia or fungal rhinitis because similar changes such as turbinate destruction and soft-tissue opacification of the nasal passages and frontal sinus may be seen in each of these diseases. Nasal CT is recommended because it greatly enhances the ability to differentiate inflammatory from neoplastic diseases. Nasal CT lesions with idiopathic chronic rhinitis may be completely unremarkable or disclose unilateral or bilateral mild-to-moderate turbinate destruction with mucus accumulation within air passages and sinuses (see Fig. 139-2). Occasionally the turbinate destruction may be severe, mimicking that seen with fungal rhinitis. Destruction of the nasal septum, frontal sinuses, or cribriform plate or extension of soft-tissue density into the nasopharynx or periorbital region is not expected with idiopathic chronic rhinitis. These findings should prompt investigation into fungal rhinitis or neoplastic disease.

The most common rhinoscopic abnormalities seen are unilateral or bilateral erythema or hyperemia and edema of the nasal mucosa with the presence of mucopus within air passages. Turbinate atrophy or loss is appreciated occasionally. Nasal samples for microbial culture are neither informative nor recommended. Histologic changes include mild-to-severe lymphoplasmacytic inflammation with occasional infiltration of neutrophils or eosinophils. Turbinate remodeling or destruction may be absent or vary from mild to severe. The severity of histologic changes may show discordance between the right and left sides of the nasal cavity.

Treatment for idiopathic lymphoplasmacytic rhinitis is extremely frustrating, with cure rarely achieved. Although this is not a life-threatening disease, owners of dogs so affected are often distraught by their pet's nasal obstruction or the need to frequently clean up nasal discharge or nasal hemorrhage within the house. Allergen avoidance is rarely helpful; however, avoidance of secondhand smoke can substantially reduce signs in some dogs. Despite earlier reports in the literature, systemic or topical corticosteroids are seldom effective in controlling clinical signs and actually may worsen them. Antihistamine medications are rarely effective, but they occasionally slightly reduce the severity of nasal discharge. Long-term administration of antibiotics with immunomodulatory effects combined with nonsteroidal antiinflammatory agents can be helpful in some dogs. Doxycycline 3 to 5 mg/kg every 12 hours orally or azithromycin 5 mg/kg every 24 hours orally in combination with piroxicam 0.3 mg/kg every 24 hours orally is recommended. If distinct clinical improvement is observed in 4 to 8 weeks, daily piroxicam therapy is continued; but the frequency of administration of doxycycline is reduced to once daily or azithromycin reduced to twice weekly. Therapy likely will be required for a minimum of 6 months if not indefinitely.

I am currently investigating itraconazole therapy in dogs refractory to other therapeutic modalities. Nasal biopsies from dogs with lymphoplasmacytic rhinitis have been reported to display an elevated transcription of fungal genes compared to dogs with nasal neoplasia using polymerase chain reaction techniques. Whether hypersensitivity to commensal nasal fungal organisms is involved or molecular techniques are detecting entrapment of fungal organisms is unclear. Preliminary experience with the administration of itraconazole 5 mg/kg every 12 hours orally for a minimum of 3 to 6 months has shown dramatic beneficial improvement and even resolution of signs in some dogs with this disease.

Nasal Neoplasia and Nasal Polyps

Nasal neoplasia is an important cause of chronic nasal disease in middle-aged to older dolichocephalic and mesocephalic dogs (McEntee, 2004). Nasal neoplasia accounts for approximately one third of all dogs with chronic nasal disease, and tumors of epithelial origin cause about two thirds of these neoplasms. The majority of nasal tumors are malignant and primarily arise within the nasal cavity, although occasionally they originate in the paranasal sinuses. Nasal tumors tend to be invasive with local- to widespread destruction of nasal turbinates seen initially and invasion of septal, cribriform, or facial bones observed later in the course of disease. Metastasis to regional lymph nodes or lung may occur, but this is rare and generally occurs in the very late stages of disease. Clinical signs are related primarily to obstruction of air flow through the nasal cavities, mucopurulent nasal discharge, epistaxis, sneezing, and sometimes reverse sneezing. Facial deformity or swelling, exophthalmia, or neurologic signs may stem from tumor destruction of facial bones or the cribriform plate. Facial pain and head shyness are rarely seen (unlike that with fungal rhinitis). In some patients initial clinical

signs may be very subtle, with unexplained onset of snoring and occasional reverse sneeze reported.

For dogs presenting primarily for epistaxis, a coagulation profile, complete blood count with platelet count, blood pressure, and serum proteins should be evaluated initially to rule out coagulopathy, hypertension, and hyperviscosity syndromes as causes of epistaxis. Nasal radiographs frequently are insensitive for subtle lesions, and radiographic changes seen with nasal tumors often overlap with those of lymphoplasmacytic and fungal rhinitis. Nasal CT is a vastly superior imaging modality for differentiating neoplastic from nonneoplastic disease and detection of bone destruction and neoplastic extension into surrounding structures (see Figs. 139-3 and 139-4). Nasal CT also is needed for tumor staging, delineating tumor boundaries, and planning radiation therapy. Three-dimensional reconstructions of the CT study may clarify the extent of bone destruction in situations in which subtle bony lesions are present (see Fig. 139-5). Thoracic radiographs are recommended when nasal neoplasia is identified before radiation therapy to rule out metastatic lung disease. Retroflex nasopharyngoscopy is useful to evaluate the nasopharyngeal region and identify tumor extension through the caudal nares. Anterior rhinoscopy in dogs with nasal neoplasia may reveal a mass lesion protruding within and occluding nasal air passages. Multiple biopsies of masses should be obtained to increase the likelihood of diagnosis because severe inflammation often surrounds nasal tumors and can create a false-negative biopsy result. Frequently nasal tumors cannot be visualized during rhinoscopy because of hemorrhage or because the origin is inaccessible. In these situations nasal CT studies facilitate direction and location for blind biopsy sampling of the affected region of the nose.

Radiation therapy is the treatment of choice for most nasal tumors. Surgery alone is ineffective, with survival times similar to those observed in untreated dogs. Cytreductive surgery is recommended before orthovoltage radiation therapy but not for cobalt or linear accelerator therapy. There is evidence suggesting that exenteration of the nasal cavity significantly prolongs the survival time in dogs with intranasal neoplasia that have previously undergone accelerated radiotherapy (Adams et al., 2005). However, exenteration after radiotherapy may increase the risk of chronic complications, including development of chronic or recurrent rhinitis and osteomyelitis. Cisplatin is used occasionally as a radiation sensitizer in radiotherapy protocols. Depending on the mode of radiation therapy available, approximate median survival times are between 16.5 to 23 months, and approximate 1-year survival rates are between 54% to 60% in dogs with nasal neoplasia. Results with cryosurgery, either alone or in combination with radiation therapy, have been disappointing; therefore it is not recommended. There is limited information on the response of nasal tumors to chemotherapy alone. The median survival in a very small group of dogs with nasal adenocarcinoma given cisplatin alone was 20 weeks, which is comparable to no treatment.

Polyps within the nasal cavity are very rare in dogs. These are usually unilateral, and rhinotomy is required for removal of the polypous tissue and surrounding

conchae. Recurrence 1 to 2 years later is possible. To date in all dogs I have seen with an initial diagnosis of a polyp, careful review of nasal CT has demonstrated localized turbinate destruction, and the subsequent histologic diagnosis following surgical resection of the polypous tissue has been low-grade fibrosarcoma associated with moderate-to-severe chronic inflammation.

CHAPTER 140

Rhinitis in the Cat

LYNELLE R. JOHNSON, *Davis, California*

Feline chronic rhinosinusitis (CRS) is a disease with high morbidity in the feline population. Despite the commonality of the syndrome, much remains unknown regarding the etiopathogenesis of disease. Multiple clinical reports have implicated involvement of feline herpesvirus type 1 (FHV-1) in CRS; however, the high prevalence of infection with this virus and the ability of the virus to cause latent infection in the feline population have made it difficult to demonstrate a causal relationship between the presence of virus and disease (Maggs et al., 1999; Johnson et al., 2005). In addition, cats with CRS often demonstrate improvement or lessening of clinical signs in response to antibiotics, suggesting that bacterial species or products of bacterial infection play a role in disease. It is possible that severe early viral infection, viral persistence within nasal epithelium, or chronic reactivation of FHV-1 into nasal tissues damages the respiratory epithelium and results in mucus accumulation, sneezing, and ultimately turbinate destruction. Viral damage might

allow bacterial invasion of nasal tissue, resulting in further turbinate destruction via bacterial and inflammatory products.

Management of cats with rhinosinusitis is challenging, and a clinically relevant question must be answered for individual affected animals: when in the course of disease should advanced diagnostic testing be performed? CRS should be considered a *disease of exclusion*, and some cats may have nasal disease requiring specific treatment. Nasal cryptococcosis or aspergillosis, foreign body disease, dental-related nasal disease, and nasal neoplasia can all result in chronic nasal discharge; and these diseases should not be overlooked. Immune suppression related to feline immunodeficiency virus infection should be ruled out. In addition, consideration should be given to the therapeutic value of nasal lavage in the management of affected cats, and this procedure is easily performed following imaging and rhinoscopy with biopsy. Therefore I recommend performing diagnostic testing

within 6 to 12 months of unsuccessful therapeutic trials, even if idiopathic disease is the most likely diagnosis.

CLINICAL FINDINGS

Chronic rhinosinusitis affects all ages of cats, with clinical signs first apparent in cats anywhere from 6 months to 20 years of age. Stertor, mucopurulent or hemorrhagic nasal discharge, and sneezing are the most common historical complaints and clinical signs, although some cats exhibit only mucoid or serous discharge. Nasal discharge is often bilateral; however, some cases are remarkably unilateral. In acute upper respiratory tract disease, ocular signs are common; however, in the chronic syndrome these are usually absent. In addition, cats with chronic upper respiratory tract disease are systemically well compared to cats or kittens with the acute syndrome, which is often accompanied by fever, inappetence, and malaise.

Cats with CRS generally have preservation of nasal airflow compared to cats with neoplasia or nasal cryptococcosis in which airflow can be obstructed by a mass lesion. Airflow can be assessed by holding a wisp of cotton up to each nostril and noting movement by air or by alternately occluding each nostril and observing the cat for difficulty in respiration. The soft palate should be palpated for abnormalities because a nasopharyngeal mass often can be felt as a space-occupying lesion dorsal to the soft palate that provides resistance to dorsal compression. Lymph nodes generally are normal in cats with CRS, although rarely enlarged mandibular nodes are detected as a result of lymphoid reactivity. In these situations it is essential to aspirate the nodes to rule out fungal disease or neoplastic infiltration. Differential ocular retropulsion in a cat with unilateral nasal discharge should be considered suspicious for neoplasia rather than CRS.

DIAGNOSIS

The diagnosis of CRS is one of exclusion. The recommended diagnostic approach involves an assessment of the extent of systemic illness with a minimum database and cryptococcal antigen test. In cats with hemorrhagic nasal discharge, blood pressure evaluation and a coagulation panel should be performed before anesthesia. Evaluation of the nasal cavity is performed to rule out conditions that mimic rhinosinusitis such as nasal foreign body, neoplasia, or fungal infection.

In the cat with chronic rhinitis, skull radiographs or computed tomography should be performed under general anesthesia to ensure optimal positioning. These show variable degrees of turbinate lysis and increased fluid density within the nasal cavity. Disease is usually bilateral, but some cases are remarkably unilateral. The middle ear or the sinuses are sometimes involved in the disease process or may be fluid filled. In many cases the severity of radiographic or tomographic changes overlap with those typically found in nasal neoplasia, making biopsy differentiation crucial (Schoenborn et al., 2003).

Rhinocopy with biopsy is performed after imaging has been completed to avoid causing hemorrhage that would alter the radiologic appearance of the nasal cavity. First nasopharyngoscopy is accomplished by retroflex of

a flexible endoscope above the soft palate. This technique is recommended to rule out the possibility of nasopharyngeal stenosis, foreign body, or a mass lesion. Rhinoscopy of the nasal cavity is best performed using a small (2.8-mm) rigid telescope. The examiner should search for evidence of primary nasal disease, including fungal plaques or neoplasia. In general cats with CRS have hyperemic mucosa, large amounts of mucoid-to-purulent discharge, and irregular turbinate structures, although some affected cats have minimal visual changes. Destructive rhinitis is evident as increased space between the turbinates. Rhinoscopic appearance does not predict the presence or absence of substantial inflammation, and bilateral nasal biopsy is recommended to assess the type and severity of inflammation.

Cats with chronic rhinitis have potential pathogens isolated from nasal samples more commonly than do normal cats (Johnson et al., 2005). Deep nasal swabs or biopsy specimens for bacterial culture (aerobic, anaerobic, and *Mycoplasma*) are sometimes helpful in guiding antibiotic therapy for secondary bacterial rhinitis. Bordetellosis can be diagnosed when the organism is isolated from nasal secretions of a symptomatic cat. Some laboratories recommend transport of the sample in Amies medium for successful culture of *Bordetella* or *Mycoplasma*.

Histologic evidence of nasal inflammation is virtually always present in cats with CRS, with the majority of severe cases demonstrating neutrophilic inflammation. Lymphoplasmacytic inflammation is noted in some cats, whereas in my experience eosinophilic infiltrates are relatively uncommon. The significance of the varying types of inflammation has not been investigated, although it is tempting to relate eosinophilic inflammation to potential FHV-1 related disease, given the association between eosinophilic inflammation and herpesvirus infection in facial dermatitis of cats (Hargis et al., 1999).

After rhinoscopy, dental probing is performed to identify oronasal fistulae or large periodontal pockets that could be responsible for dental-related nasal disease.

THERAPY

Antibiotics

Chronic antibiotic therapy is usually prescribed in an attempt to control secondary bacterial rhinitis. Choice of antibiotics for the individual cat can be based on culture of a deep nasal flush or biopsy sample or may be made based on an understanding of potential pathogens that have been isolated previously from cats with rhinitis. These organisms include aerobes (*Pasteurella multocida*, *Escherichia coli*, *Corynebacterium ulcerans*, *Bordetella bronchiseptica*, *Streptococcus viridans*, *Pseudomonas aeruginosa*, *Actinomyces slackii*), anaerobes (*Peptostreptococcus anaerobius*, *Bacteroides fragilis*, *Bacteroides ureolyticus*, *Prevotella*, *Fusobacterium nucleatum*), and *Mycoplasma felis* (Johnson et al., 2005). I prefer doxycycline (approximately 50 mg/cat orally divided every 12 hours or given once daily) because it has efficacy against these bacteria, as well as in vitro efficacy for *Bordetella*. In addition, doxycycline may help control clinical signs through antiinflammatory or immunomodulatory effects. Doxycycline is readily available, well tolerated by most cats even when administered

long term, and inexpensive. The primary caution with use of this drug is the potential for induction of an esophageal stricture if the pill lodges in the esophagus. Instruction labels should always contain the recommendation to follow administration of the pill with a small volume of water or food.

Most isolates of *Bordetella* are susceptible in vitro to tetracycline, doxycycline, and enrofloxacin; but resistance to tetracyclines has been reported. Oral antibiotic treatment generally reduces clinical signs, but it does not eliminate shedding of bacteria. Some cats remain as chronic carriers of the organism and are culture positive. It is unclear whether these cats are chronic or intermittent shedders of the organism into the environment. Improving cleanliness, ventilation, and husbandry in an affected cattery or shelter should help limit spread of disease. If *Bordetella* is documented in a cat and the animal does not respond to oral antibiotics, use of topical gentamicin (Gentocin, Schering-Plough) (intra-nasal drops or nebulization) should be considered since this method is more likely to reduce bacterial numbers.

Other commonly used antibiotics include azithro-mycin, cephalexin, and amoxicillin-clavulanic acid. Azithromycin is an appealing option because it is available in liquid form and can be given once daily for 3 to 5 days at 5 mg/kg and then twice weekly because of its ability to accumulate in tissue. Penicillin-like drugs are efficacious in many cats, although they lack efficacy against *Mycoplasma* spp., which are cell wall-deficient organisms. These drugs are also frequently associated with gastrointestinal side effects. Enrofloxacin (Baytril [Bayer], 2.5 mg/kg orally every 24 hours) generally is reserved for infections that are susceptible to this antibiotic, and high doses are to be avoided since they have been associated with a type of toxic retinopathy. Clindamycin can be efficacious in cases with extensive bony involvement because of its ability to penetrate bone. Antibiotic treatment usually is continued at the full dose for at least 3 to 6 weeks based on the assumption that turbinates are infected. In cats with recurrent clinical signs, intermittent treatment with antibiotics (1 week of each month) or suppressive antibiotic therapy (once daily administration of drug) may be required.

Antiinflammatory Agents

Control of nasal inflammation can sometimes be achieved with the use of piroxicam at 0.3 mg/kg orally daily or every other day. This drug is commercially available as a 10-mg tablet, and drug compounding is required. This nonsteroidal antiinflammatory causes subclinical gastric erosion, and caution is warranted in its use in older animals or in cats with renal insufficiency. Meloxicam is a tempting alternative to piroxicam because it is easier to dose and administer, although subjectively cats do not appear to respond as well to it.

Glucocorticoids are sometimes advocated for treatment of cats with CRS, and in severely affected animals with inspissated mucus in the nasal cavity administration of oral steroids may reduce mucus accumulation and promote appetite. Inhaled or topical steroids are sometimes used, although it would seem wise to clear all mucus from the nasal cavity before use to provide a mucosal surface area for local absorption and action. Liquid steroid medications are available in drop formulations or as nasal

sprays. Metered-dose inhaler preparations containing steroids such as fluticasone require administration with a spacer chamber and face mask.

Antihistamine administration might improve clinical signs in some cats, although these drugs can also cause excessive drying of respiratory secretions. Multiple over-the-counter preparations are available, and individual cats can show variable response to different types of antihistamines.

Antiviral Therapy

The role of FHV-1 in induction or promotion of clinical signs in cats with CRS has not been clearly established, and specific antiviral therapy is not recommended in cats with chronic disease. A novel antiviral therapy that is unlikely to result in harmful side effects is dietary supplementation with lysine, an amino acid that competes with arginine for use by the viral machinery in replication. The recommended dose of lysine is 500 mg/cat orally twice daily; this dose does not result in a drop in serum arginine levels in the cat. Lysine can be purchased at most health food stores as a pill or a capsule containing granules, and veterinary paste formulations are also available. Trial therapy with lysine should be considered in any cat with CRS and is particularly indicated when intranuclear inclusions are detected or an eosinophilic inflammatory infiltrate is reported on histology.

ADDITIONAL THERAPY

Rigorous flushing of the nasal cavity when the animal is anesthetized for diagnostic testing undoubtedly improves the clinical demeanor of cats with CRS. Cats can also benefit from intermittent airway humidification via steam inhalation or nebulization.

PROGNOSIS

It seems unlikely that cats with CRS can be cured given the abnormalities that are often found in nasal anatomy by the time veterinary intervention is sought or diagnostics are typically performed. Owners should be aware that this disease can often be controlled but is rarely cured. Most cats have recurrent episodes of nasal discharge periodically, and a reasonable goal of therapy is to limit the severity and frequency of disease exacerbations.

Brachycephalic Upper Airway Syndrome in Dogs

ERIC R. POPE, *Bassesterre, St. Kitts, West Indies*

GHEORGE M. CONSTANTINESCU, *Columbia, Missouri*

The brachycephalic upper airway syndrome is a group of congenital and acquired abnormalities of the upper airway that results in signs of upper airway obstruction. Congenital anatomic abnormalities encountered include varying degrees of stenotic nares; shortening, widening, and flattening of the nasal cavity and pharynx, causing increased airway resistance; elongation, thickening, and flaccidity of the soft palate; and decreased glottic size. These animals may also have a hypoplastic trachea, which adds to the increased airway resistance. Acquired abnormalities resulting from the greatly increased inspiratory effort include edema and further thickening of the soft palate, eversion of the laryngeal sacculs, edema of the pharyngeal and laryngeal mucosa, enlargement of the tonsils, and progressive laryngeal dysfunction ending with complete laryngeal collapse.

The English bulldog, pug, Boston terrier, chow-chow, Pekingese, Shih Tzu and shar-pei are commonly affected breeds. Stenotic nares may also occur in short-nosed breeds of cats such as the Persian and Himalayan. Progressively worsening inspiratory dyspnea, which is exacerbated by exercise, is the most common clinical sign. If stenotic nares are the primary pathology, the clinical signs are relieved by open-mouth breathing. Coughing, gagging, and stridor generally are associated with elongated soft palate and/or acquired abnormalities of the pharyngeal/laryngeal area.

A complete upper airway examination should be performed before undertaking surgical correction of any of these problems. The nares and soft palate usually can be evaluated in the awake patient, but adequate visualization of the pharynx and larynx typically requires sedation or anesthesia. If a light plane of anesthesia is maintained, stimulation of the laryngeal mucosa induces deep respiratory efforts, making assessment of the ability of the laryngeal cartilages to abduct easier. Deep respirations can also be induced by the administration of doxapram (1 mg/kg intravenously [IV]). In most instances surgical correction immediately follows the examination. The prognosis is largely determined by the severity of the secondary changes, especially laryngeal dysfunction. If the laryngeal changes are limited to eversion of the laryngeal sacculs and edema of the mucosa, marked improvement is usually seen following correction of the underlying anatomic abnormalities and excision of the everted sacculs.

Surgical treatment usually includes correction of the stenotic nares, resection of excessive soft palate, and amputation of the everted laryngeal sacculs. If respiratory distress continues after surgery because of poor laryngeal

function, partial arytenoidectomy and vocal fold resection can be performed, but the results are quite variable (see Chapter 143). Respiratory distress may continue because of further collapse of the weakened cartilages. Permanent tracheostomy is the best means of providing an adequate airway in animals with severe laryngeal collapse but can be challenging because of the loose, redundant skin on the neck and the small size of the trachea.

STENOTIC NARES

Stenotic nares greatly increase airway resistance. Surgical correction should be performed as soon as possible (i.e., 3 to 4 months of age) to reduce the development of the secondary changes previously described. Correction involves lateralization of the wing of the nostril (alar wing) and possibly resection of a portion of the alar fold to increase the size of the nares. Vertical, horizontal, and dorsolateral wedge resection techniques and amputation of a portion of the alar wing have been described. Recently an alapexy technique was described that might potentially maintain long-term lateralization better than other surgical methods. This method has been used by some surgeons for both primary reconstruction and when the other techniques have failed. Selection of specific technique is based on both manipulation of the alar wing once the patient has been anesthetized and surgeon preference.

The vertical and horizontal wedge techniques are performed using a No.11 scalpel blade or CO₂ laser. The alar wing to be removed is grasped with Brown-Adson thumb forceps. The scalpel blade is used to remove a wedge (ellipse) of tissue sufficiently wide to relieve the obstruction. The cut must also be deep enough to allow rotation of the ventral (medial) portion of the alar wing. Since hemorrhage may be brisk, it is important to assess the amount of tissue that needs to be removed and then resect it with single bold strokes. Digital pressure and/or wound closure is usually sufficient to control bleeding. The use of electrocautery should be avoided. The edges are sutured with fine (4/0 to 5/0) monofilament suture material in an interrupted pattern. The sutures are tied only tight enough to appose the edges. Excessive tension may result in discomfort, causing the animal to rub the sutures. If bleeding continues after placing the sutures, digital pressure is applied for 5 to 10 minutes.

The dorsolateral wedge technique is preferred by many veterinary surgeons over the vertical and horizontal wedge techniques. An ellipse of tissue is removed at the

junction of caudal alar wing adjacent to the haired skin. Most of the tissue is removed from the alar wing. Again it is important to make the wedge deep enough to allow lateralization of the alar wing. This generally means going down almost to the nasal mucosa. The alar wing is sutured to the adjacent skin with fine monofilament suture material. If the alar fold is prominent and restricts the opening into the nasal cavity, it can be excised as described in the following paragraphs.

A potential complication of the wedge techniques is collapse of the ala and recurrence of signs over time. The alapexy technique is suggested as a more effective technique for preventing this complication. Two approximately 5- to 10-mm long \times 3-mm wide \times 3-mm deep strips of skin are removed from the ventrolateral aspect of the alar wing and from the haired skin 3 to 5 mm lateral to the alar wing. The alar wing is lateralized to appose the wound edges. The adjacent deep wound edges are sutured with interrupted or continuous sutures using monofilament absorbable suture. The adjacent outer wound edges are sutured with interrupted or cruciate sutures using monofilament absorbable or nonabsorbable suture material.

The CO₂ laser also can be used to correct stenotic nares. Hemorrhage is reduced significantly, improving visualization. In small dogs and cats the ventromedial portion of the alar wing is amputated, and the wound is allowed to heal by second intention. In larger dogs wedge resection can be performed as described previously. Similar to the original amputation technique performed with a scalpel, the cosmetic result of amputation by laser resection may not be as good as with the other techniques but is generally very acceptable to the owner.

Some patients have a very prominent alar fold that compromises the opening of the nostril even when the alar wing is adequately lateralized or removed. This can cause significant resistance to airflow and should be addressed if present. The CO₂ laser is an excellent tool for excising a portion of the alar fold. The hemostasis provided improves visualization and control of the amount of tissue removed. The tissue can also be removed with a scalpel blade, but bleeding impairs visualization. Bleeding is controlled by applying pressure.

ELONGATED SOFT PALATE

In the normal animal the caudal border of the soft palate slightly covers the tip of the epiglottis. In patients with brachycephalic airway syndrome, the soft palate may become so elongated that it is sucked into the laryngeal aditus during inspiration. The goal of the surgery is to reestablish the normal anatomic relationship of the soft palate and epiglottis. Since the soft palate functions to occlude the nasopharynx during swallowing, excessive resection can result in nasal reflux, causing chronic rhinitis, and may also predispose the patient to aspiration pneumonia.

Because most patients have some edema of the pharyngeal structures and surgical manipulation of the soft palate induces more swelling, corticosteroids (e.g., prednisolone [0.5 to 1 mg/kg]) are usually given before surgery at induction. Following induction of general anesthesia, an oral speculum is placed. The base of the tongue is

depressed with the blade of a laryngoscope; the tip must not cover the epiglottis. The point at which the tip of the epiglottis touches the palate is marked with a skin marker or pinched with a hemostat. A cuffed endotracheal tube is placed. Laterally the soft palate should extend to the caudal border of the tonsillar crypt. Palatotomy can be performed with clamps used to demarcate the amount of palate to be removed or the tissue can be cut freehand using cold steel or laser.

Surgeons without access to a laser and particularly those with minimal experience will likely be more comfortable performing the clamp technique described next. It is easier to perform than the freehand techniques because there is more control of the cut, particularly when the palate is thickened; but it is also the most traumatic technique. Curved hemostats or right-angle Meeker forceps are placed across the soft palate from the caudal border of the tonsillar crypt to the mark on the midline of the soft palate on each side so that tips oppose each other. The distal portion of the palate is excised along the clamp with a scalpel; or alternatively the clamp can be removed from one side, and the palate cut with scissors along the line of crushed tissue. When this technique is used, our preference is to excise all the excess palate with a scalpel, remove the clamp from one side, and then suture the oral and nasopharyngeal mucosa of the palate with a continuous pattern using fine (4/0 to 5/0) absorbable monofilament suture material. When the midpoint is reached, the clamp is removed from the other side, and suturing continued from the midline laterally. Although the clamp technique is more traumatic than the noncrush "cut and sew" technique described next, when the clamps are used it is much easier to control the amount of palate resected and to establish a smooth curve to the caudal border of the soft palate.

The freehand "cut and sew" technique is less traumatic than the clamp technique and is recommended if a laser is not available. A suture is placed at the caudal border of the tonsillar crypt on one side. The palate is grasped at the midpoint with forceps and retracted rostrally. The palate is cut with scissors from the lateral border to the midline. It is sutured with a continuous pattern (as described previously) to the midpoint. The other side of the palate is then excised and sutured. Performing the procedure in two steps facilitates tissue manipulation and reduces the amount of hemorrhage.

Resection of the soft palate using the CO₂ laser is the least traumatic technique. An advantage of the laser is that minimal manipulation of the palate is required. Saline-moistened sponges are placed in the pharynx and behind the palate after determining the amount of palate to be resected. The palate is then excised freehand beginning laterally on one side and then working across to the opposite side. A long-handled thumb forceps (e.g., DeBakey forceps) can be used to grasp the caudal edge of the palate while it is being cut with the laser. Some surgeons prefer to use a handpiece with a backstop to further minimize the risk of collateral damage. Because minimal manipulation of the soft palate is necessary, it is much easier to maintain orientation during the resection. Suturing is not necessary when the laser is used, and hemorrhage is usually negligible.

EVERTED LARYNGEAL SACCULES

The laryngeal ventricles are small pockets in the wall of the larynx just rostral and lateral to the vocal folds. With chronic increased respiratory effort, the mucosa of the ventricles can evert. As the tissues become edematous, they protrude into the laryngeal aditus and appear as small pea-shaped masses just in front of the vocal folds. The everted saccules can be grasped with forceps and then amputated at their base with long-handled scissors. Hemorrhage is usually minimal and controlled by pressure. Cotton swabs soaked with dilute epinephrine can also be used if bleeding occurs. The mucosal defects heal by second intention.

LARYNGEAL COLLAPSE

If the underlying conditions are not recognized and treated early, the chronically increased inspiratory effort ultimately can lead to progressive distortion and complete collapse of the laryngeal cartilages. Eversion of the laryngeal saccules is considered to be the first step in the pathogenesis of laryngeal collapse (stage 1). As the condition progresses to stage 2 the cuneiform processes rotate medially, and there may be only minimal or no abduction of the arytenoids when viewed during laryngoscopy. In stage 3 complete loss of support occurs so that the corniculate and cuneiform processes may abut each other medially or even overlap. The latter change carries a poor prognosis, and permanent tracheostomy is the most successful treatment.

If only minor laryngeal dysfunction is noted (stage 1), the other upper airway abnormalities are corrected as previously described, and the animal is allowed to recover. If respiratory distress persists or progresses, laryngeal surgery or permanent tracheostomy is indicated. All patients undergoing laryngeal surgery should receive corticosteroids before surgery unless temporary tracheostomy is performed. Everted laryngeal saccules are amputated if this has not been previously done.

Partial Arytenoidectomy and Vocal Fold Resection

Dogs with stage 2 collapse (cartilages are collapsing medially, but some glottic lumen remains) may improve

following partial arytenoidectomy and vocal fold resection. Partial arytenoidectomy can be performed unilaterally or bilaterally. Partial arytenoidectomy is performed via an oral approach using long-handled instruments such as a uterine biopsy forceps to remove small bites from the medial wall of the corniculate processes. If bilateral partial arytenoidectomy is performed, the incidence of postoperative stricture can be reduced by not extending the arytenoidectomy to the dorsal midline. Excessive removal of tissue, particularly when done bilaterally, may predispose to aspiration pneumonia. Bilateral resection of the vocal folds is also performed using the uterine biopsy forceps. Postoperative stricture ("webbing") is decreased if the ventral commissure of the vocal folds is left intact.

Permanent Tracheostomy

Permanent tracheostomy is indicated in animals with stage 3 collapse and patients that do not improve following partial arytenoidectomy and vocal fold resection. Permanent tracheostomy entails removing the ventral third of the tracheal cartilages over a 3- to 4-tracheal ring span and suturing the tracheal mucosa to the skin. During the initial postoperative period the tracheostoma should be checked every 1 to 3 hours for mucus accumulation and cleaned as needed. The amount of mucus produced gradually decreases so that long-term cleansing is necessary only one to three times daily. The hair of long-haired dogs should be kept trimmed to prevent matting with mucus, which could occlude the stoma. Some stenosis of the opening is expected. Dogs with permanent tracheostomy are predisposed to inhaled foreign bodies and obviously cannot be allowed to swim, but otherwise they seem to function well.

Nasopharyngeal Disorders

GERALDINE B. HUNT, *Sydney, Australia*

SUSAN F. FOSTER, *Murdoch, Australia*

A variety of nasopharyngeal diseases are encountered in small animals. In cats nasopharyngeal disease is most commonly caused by cryptococcosis (dependent on location), nasopharyngeal polyps, neoplasia, and foreign bodies. In dogs nasopharyngeal disease may be caused by inflammation, neoplasia, foreign bodies, nasal mites (*Pneumonyssoides caninum*) or congenital abnormalities. Since clinical signs of disease resulting from different etiologies may be identical, a thorough and systematic approach to diagnosis is required to ensure that treatable diseases are not missed.

CLINICAL SIGNS OF NASOPHARYNGEAL DISEASE

Animals with disease limited to the nasopharynx present mainly with signs of upper airway obstruction (i.e., stertor/snoring). In dogs stertor is usually alleviated by open-mouth breathing. Cats are often unwilling or unable to breathe through their mouths and thus may appear dyspneic. Some animals show signs of pharyngeal discomfort and make repeated attempts at swallowing; coughing and dysphagia may occur in cats. A cat with acute nasopharyngeal disease may paw at its nose and mouth. Dogs may also present with facial discomfort and pruritus. Reverse sneezing is a specific nasopharyngeal sign in dogs. Purulent nasal discharge and fetid breath may be identified in animals with foreign bodies.

Unless nasopharyngeal disease is accompanied by significant intranasal pathology, nasal discharge is usually mild or absent because secretions from the nasopharynx tend to be swallowed. Likewise, sneezing is not typical but may occur if the caudal nasal turbinates are irritated or if disease also affects the nasal cavity.

Enlargement of regional lymph nodes, in particular the mandibular and retropharyngeal nodes, may be the first detectable clinical sign in animals with nasopharyngeal neoplasia. Occasionally the main presenting signs are neurologic. Central nervous system signs may result from the spread of nasopharyngeal cryptococcosis or neoplasia. Signs of otitis media and vestibular disease may occur if there is extension of disease from the nasopharynx into the tympanic bulla (or vice versa) or if the opening to the eustachian tube is occluded. Horner's syndrome is encountered commonly in cats with involvement of the tympanic bullae. Animals with inflammatory or neoplastic disease extending beyond the tympanic bulla may also have signs of facial nerve dysfunction (facial asymmetry, absent palpebral reflex).

The duration of onset and severity of signs vary according to the underlying disease. Rapid onset of signs is suggestive

of a nasopharyngeal foreign body, although some patients with foreign bodies have chronic signs. Gradual onset of stertor and attempted mouth breathing is more likely to indicate a slow-growing nasopharyngeal mass.

DIAGNOSIS OF NASOPHARYNGEAL DISEASE

Because of difficulties of access and the complex anatomy of surrounding structures, diagnosis of nasopharyngeal disease may be challenging. In the past investigation was often limited to digital palpation through the soft palate and visualization under anesthesia using dental mirrors and spay hooks. However, now many techniques of varying complexity are available to the veterinary practitioner.

Physical Examination

In quiet patients palpation through the soft palate may reveal masses in the nasopharynx. Regional lymph nodes should always be palpated and, if affected, may provide a convenient source of diagnostic material. Mucous membrane color should be evaluated for evidence of cyanosis, which may indicate serious respiratory compromise. Determination of oxygen saturation by means of pulse oximetry should be considered where available. Cardiopulmonary function should be evaluated carefully to rule out the possibility of intrathoracic disease in animals displaying signs of respiratory dysfunction. Likewise, an attempt should be made to differentiate stertor (a snoring-type noise arising from the nasopharynx or pharynx) from stridor (a high-pitched noise arising from disturbance of air flow through the larynx or trachea) before physical or chemical restraint. If possible, the effect of opening the mouth on stertor should be determined.

Direct Visualization of the Nasopharynx

If nasopharyngeal or caudal nasal disease is suspected, further evaluation under general anesthesia is required. Anesthesia is ideally induced using an intravenous technique enabling rapid airway control and maintained subsequently by inhalation agents in oxygen. The oropharynx, laryngopharynx, and larynx are inspected initially before placement of a cuffed endotracheal tube. When performing manipulations that may cause blood or other fluid to accumulate in the pharynx, it is critical that the cuff be inflated to ensure a leakproof seal and that the laryngopharynx be packed with gauze. The animal is best positioned in dorsal recumbency, with the maxilla held down firmly with

tape applied over the upper canine teeth. Topical anesthesia of the nasopharynx is instituted with a small amount of local anesthetic (lidocaine, 1 mg/kg topically by means of a soaked surgical swab placed in the pharynx or trickled down from the external nares via the ventral nasal meatus). This avoids the necessity of deepening the plane of anesthesia excessively to abolish reflexes resulting from mechanical stimulation of sensitive nasopharyngeal structures. The nasopharynx is examined by palpation through the soft palate, followed by rostral retraction of the caudal edge of the soft palate using a spay hook. The caudal part of the nasopharynx is relatively well exposed in this fashion. The cranial nasopharynx and choanae can also be visualized in cats but not usually in dogs.

Nasopharyngeal Endoscopy

The mainstay of diagnosis of nasopharyngeal disease is retroflexed endoscopy. A flexible endoscope (appropriate to the size of the animal) is introduced into the pharynx and retroflexed above the soft palate. In some instances it may be simpler to retroflex the endoscope before insertion, introduce it into the pharynx and proximal esophagus, and then hook it above the soft palate. Rostral retraction, so that the retroflexed end advances towards the nose, enables visualization of the rostral nasopharynx, choanae, and caudal nasal cavities. Mass lesions may be apparent immediately; although in some cases lesions are obscured by mucus, blood, or pus. Vigorous flushing with saline (via the endoscope or through the nostrils) usually clears the field sufficiently to allow visualization of lesions. A technique of nasopharyngoscopy using an endoscope inserted via gastrotomy has been reported recently (Esterline, Radlinsky, and Schermerhorn, 2005) for use in situations in which a flexible endoscope of the size appropriate for a cat is not available. Since it involves a surgical approach to the stomach, this technique would only be recommended if no other means of visualizing the nasopharynx were practical.

Diagnostic Imaging

The normal nasopharynx is readily identified on plain lateral radiographs because of the presence of air dorsal to the soft palate. The hyoid apparatus and larynx define its caudal boundary. Space-occupying lesions of the nasopharynx may be delineated by surrounding air, and radiopaque objects may be apparent. However, because of the complex anatomy of the region, the presence of objects such as endotracheal tubes and esophageal stethoscopes, and secretions within the nasopharynx, radiographic details may be obscured. Positive-contrast studies of the nasal cavity and nasopharynx have been largely supplanted by endoscopy. In general, radiography provides little more information than thorough examination under anesthesia and palpation through the soft palate.

Ultrasonography can be useful in animals with soft tissue or fluid-filled masses in the nasopharynx and assist the acquisition of diagnostic samples using ultrasound-guided needle aspiration or biopsy. Large vascular structures may be present in some cases; thus Tru-Cut or incisional biopsies should be taken with care. Advanced

imaging techniques such as computed tomography and magnetic resonance imaging are potentially useful for detecting nasopharyngeal lesions, determining precise anatomic information, and assessing involvement of nearby structures such as the middle ear and bones of the skull. These are also helpful in assessing tumor response to radiotherapy and/or surgery.

Obtaining Diagnostic Samples From the Nasopharynx

To make a definitive diagnosis, in many cases it is necessary to obtain representative specimens for cytology, histology, and microbial culture. Fine-needle aspiration may be performed readily through the soft palate. Blind Tru-cut biopsy of lesions through the soft palate is also technically feasible but carries a risk of inducing hemorrhage if large blood vessels lateral to the nasopharynx are perforated. Ideally tissue biopsies are obtained under direct visualization either by retracting or incising the soft palate or via endoscopic biopsy.

When a mass is present, vigorous massage of the lesion through the soft palate often dislodges or fragments the mass, and antegrade flushing via the nares may be successful in dislodging part or all of it. In dogs flushing is best achieved via soft catheters inserted into the ventral nasal meatus; however, in cats effective pressure can be generated by inserting the end of a 10-ml syringe directly into the nares and holding the nares closed with the fingers. Material dislodged from the nasal cavity or nasopharynx by flushing then bounces off the larynx or cuffed endotracheal tube to appear in the oropharynx or mouth. Antegrade passage of a catheter through the left and right ventral nasal meatus is helpful in dislodging foreign material and mucus.

Canine nasal mites may also be retrieved for diagnosis with nasal flushing, although endoscopic visualization is preferable. Flushing the nasal cavity with halothane has been reported to induce mites to migrate caudally in the nasopharynx, where they can be retrieved and identified easily (Marks, Moore, and Rishniw, 1997).

Adjunctive Tests for Diagnosis of Nasopharyngeal Disease

Cytologic examination and culture of nasal swabs may detect organisms such as *Cryptococcus* spp. Positive findings need to be interpreted carefully. Both cats and dogs can have asymptomatic carriage of *Cryptococcus* spp., and 30% to 40% of normal dogs with nasal neoplasia have *Aspergillus* or *Penicillium* spp. cultured from blind swabs (Sharp, 1998). Serology is useful to differentiate asymptomatic carriage of *Cryptococcus* spp. from infection because animals with cryptococcosis usually demonstrate a positive latex cryptococcal antigen agglutination test titer.

SURGICAL ACCESS TO THE NASOPHARYNX

When extraction of lesions such as inflammatory polyps, cryptococcal granulomas, or foreign bodies is not possible via palatine retraction or better access is required for

obtaining diagnostic samples, the nasopharynx may be approached surgically via a longitudinal incision in the soft palate. In most cases adequate access is obtained by maximally opening the jaws, placing a mouth gag, and having an assistant hold the tube out of the way with a malleable retractor. Although placement of the endotracheal tube via a pharyngostomy incision improves the working area somewhat, it takes longer and results in more postoperative morbidity.

The soft palate is divided longitudinally from the caudal edge of the hard palate to within a centimeter of its caudal free edge. The caudal edge should be left intact to facilitate repair and support the incision during healing. Some bleeding from the rich vascular plexus within the soft palate should be anticipated but usually resolves spontaneously or with digital pressure. Surgical suction and good lighting should be available, as should a surgical assistant. When extensive dissection is likely to be undertaken in dogs, blood loss may be ameliorated somewhat by temporary occlusion of the carotid arteries using Rumel tourniquets placed through a ventral midline cervical incision. This technique is not recommended for cats because they often develop neurologic sequelae. In either species if major blood loss is anticipated, contingencies for replacement with whole blood or a blood replacement product should be made. The soft palate incision may be continued rostrally as a mucoperiosteal incision and ventral rhinotomy if indicated, providing excellent access to the ventral nasal cavity. Repair of the soft palate is performed in two or three layers. Polydioxanone in a continuous suture pattern in the nasal mucosal and muscularis layer and oral mucosa provides excellent closure. Postoperative management is usually uncomplicated. Animals display little evidence of pain associated with the incision and are usually willing to eat and drink within 24 hours of surgery unless systemic illness is present. Healing in this area is rapid and reliable, presumably because of its excellent blood supply. Soft food should be offered for 2 to 3 weeks after surgery, and the incision should be examined at weekly intervals to ensure that no areas of wound dehiscence are developing.

SPECIFIC NASOPHARYNGEAL DISEASES AND THEIR TREATMENT

Nasopharyngeal Foreign Bodies

Foreign bodies may include tablets, bones, fish heads, stones, plant material (blades of grass are especially common in cats), seaweed segments, and plastic. These materials are often coated with a layer of mucus or exudate. Nasopharyngeal foreign bodies may be dislodged by digital palpation or extracted under direct vision, endoscopically, or surgically. Visualization and removal are facilitated by laying the animal on its back and extending its head before retracting the soft palate. In many cases it is possible to dislodge foreign bodies caudally with a combination of anterograde flushing and passage of a urinary catheter. Alligator forceps may also be passed anterograde and used to push the foreign body caudally for retrieval in the pharynx. Small embolectomy or cardiovascular catheters, with an inflatable balloon passed via the nares and

inflated at the choanae, can be useful to dislodge foreign bodies and push them into the pharynx. After removal of the foreign body, the nasopharynx should be flushed with saline. If local ulceration is severe, broad-spectrum antibiotics with efficacy against anaerobes may be administered for 3 to 5 days.

Nasopharyngeal Parasites

The canine nasal mite *P. caninum* is a parasite, reported from many countries (probably worldwide) that inhabits the nasal cavity, nasopharynx, and frontal sinus. Clinical signs described include sneezing, reverse sneezing, rhinitis, and impaired sense of smell. Diagnosis is established by direct observation of the mites in or around the external nares or endoscopically in the nasopharynx or nares. Nasal mites can be treated effectively with milbemycin, ivermectin, or topical selamectin. Milbemycin at 0.5 to 1 mg/kg once weekly orally for 3 consecutive weeks appears safe and efficacious; 0.5 mg/kg once monthly orally is the dose for heartworm prophylaxis (Gunnarsson et al., 1999). Selamectin at 6 to 24 mg/kg every 2 weeks topically for three treatments has also been demonstrated to be effective (Gunnarsson et al, 2004), but alopecia may develop at the higher doses; 6 to 12 mg/kg monthly topically is the dose used for heartworm prophylaxis. Ivermectin has been used at various doses (200 to 400 mcg/kg, subcutaneously [SC] or PO) and dosing frequencies (single dose or multiple doses at various intervals) and appears effective; but all doses have been higher than the licensed dose, and these doses may have serious adverse effects in ivermectin-sensitive breeds such as collies. One dog had nasal mites diagnosed while on ivermectin prophylaxis for heartworm (6 mcg/kg PO); thus lower doses may not be effective (Coleman, Walter, and Dickson, 2000). It is advisable to supply a single antiinflammatory dose of prednisolone (0.5 mg/kg PO) with the first treatment to be used either prophylactically or if signs worsen in severity after treatment. The transient increase in severity of signs that occurs in some dogs is presumed to be caused by a host reaction to the dead and dying mites. Although this reaction is only transient, it may be quite distressing to both the dogs and their owners.

Cuterebra larvae occasionally occur in the feline pharynx, most commonly in the retropharyngeal tissues but also on the soft palate. The parasite may be seen through the "breathing hole" in the mucosal surface or may be found within a resected mass lesion. *Cuterebra* larvae are removed by enlarging the breathing pore and grasping the parasite with forceps. Hypersensitivity reactions may occur if parasitic hemolymph escapes into the surrounding tissue; thus care must be taken not to damage the larva during extraction. Alternatively the entire granuloma may be excised (Levy and Ford, 1994).

Nasopharyngeal Cryptococcosis

In cats and dogs the nasal cavity is usually the primary site of infection with *Cryptococcus* spp. Rhinitis is the most common presentation, but caudal nasal cavity and nasopharyngeal involvement may occur, and nasopharyngeal signs may predominate. If nasopharyngeal

cryptococcomas are present, debulking by vigorous nasal flushing or surgery is recommended to alleviate the upper airway obstruction and decrease residual infected tissue to be treated medically. The potential danger of complete upper airway obstruction in patients with nasopharyngeal cryptococcosis should not be underestimated, especially in cats, since they tend to be reluctant to resort to open-mouth breathing. In addition, since debulking has been found to hasten resolution in some cases that are responding slowly to medical management, debulking should be considered before medical therapy. Medical treatment for nasopharyngeal cryptococcosis requires oral itraconazole or fluconazole; ketoconazole is not very effective and likely to result in adverse side effects. Amphotericin is unnecessary unless there is central nervous system involvement. Fluconazole is a very effective agent for treating cryptococcosis and is well tolerated, even at high doses, in the majority of cases. The dose of fluconazole is 30 to 50 mg per cat every 12 hours orally, with dose based on cat size. Fluconazole penetrates the blood-brain barrier even in the absence of inflammation; thus it should be used in preference to itraconazole if there is concurrent nervous system involvement. Itraconazole is used more commonly because it is effective and considerably cheaper than fluconazole. It does not penetrate the blood-brain barrier and often causes a reversible hepatotoxicity at higher doses. Itraconazole is usually administered at 50 to 100 mg per cat once daily orally with food. Medium-size to large cats should receive 100 mg once daily, whereas cats weighing 3.5 kg or less should receive 50 mg daily or 100 mg on alternate days. Many cats eventually develop liver toxicity during therapy with itraconazole at these doses. This can take several weeks to months to develop and is manifest clinically as reduced appetite and sometimes vomiting. Invariably there is increased serum alanine aminotransferase activity. Itraconazole-induced hepatotoxicity is reversible on discontinuation of the drug, although appetite and demeanor may take up to 7 days to recover. Once the cat has recovered, it is generally possible to safely administer the drug again, albeit at a reduced dose, typically 50% of the original dose. In a minority of cases it is necessary to change therapy to fluconazole. Medical therapy with either drug should be continued until resolution of all clinical signs. Typically this takes 3 to 12 months, although some cases require longer periods of treatment. The serum cryptococcal antigen titer should be monitored, and a fourfold to fivefold reduction in titer suggests successful therapy. It is highly recommended that treatment be continued until the antigen titer declines to zero.

Nasopharyngeal Polyps

Nasopharyngeal polyps occur much more commonly in cats than dogs. Nasopharyngeal polyps in cats usually arise from the eustachian tube or the middle ear. They are composed of granulation tissue covered by a stratified squamous or ciliated columnar epithelial layer that is often ulcerated. The causes of inflammatory polyps in cats are unknown. It has been proposed that they result from either congenital defects or chronic inflammatory middle ear disease probably caused by viral upper

respiratory tract infection. Clinical signs may be respiratory, otic, or both. Because of their caudal location in the nasopharynx, feline nasopharyngeal polyps are often amenable to removal by traction by an oral approach. Removal of nasopharyngeal polyps by traction is most likely to be successful if the polyp is well visualized. The animal is intubated, and the pharynx packed with gauze. A pair of grasping forceps with strong teeth is required. If they are not available, artery forceps are preferred to conventional alligator forceps. The cat is positioned in dorsal recumbency, and its head taped to the table or held by an assistant. The soft palate is drawn rostrally to visualize the polyp. The polyp is grasped firmly across as much of its body as possible, ensuring that pharyngeal mucosa is not included, and firm traction is applied. The polyp should be submitted for histopathology to confirm the diagnosis and eliminate the possibility of lymphosarcoma or cryptococcosis.

Owners should be warned of the likelihood of temporary Horner's syndrome after extraction. This usually resolves in 1 to 3 weeks. Recurrence of the polyp is possible, and some surgeons recommend ventral bulla osteotomy in all cats with this condition. However, a recent study suggested that traction/avulsion is a good first option in cats with no radiographic or computed tomography evidence of bullae involvement (Veir et al., 2002). The same study demonstrated that polyps do not always recur in cats with bulla involvement; therefore traction/avulsion is probably a reasonable first option in these cats also. Anderson, Robinson, and White (2000) showed that cats with nasopharyngeal polyps were nearly four times more likely to be cured by traction alone than cats with aural polyps and that treatment with antiinflammatory doses of prednisolone following traction reduced the recurrence rate.

In dogs polyps usually arise from the caudal nasal turbinates as a consequence of chronic rhinitis. They are usually situated rostrally in the nasopharynx, attached to the caudal nasal turbinates. This is also true of other forms of inflammatory granuloma. It may be possible to dislodge these with vigorous flushing or by grasping them endoscopically. In other cases a ventral surgical approach to the nasopharynx may be combined with a ventral rhinotomy to obtain diagnostic samples and debulk the lesions.

Nasopharyngeal Stenosis

Nasopharyngeal stenosis is most often seen in cats following chronic inflammation. Stricture formation may occur in both cats and dogs following infectious diseases, surgery, or other trauma or as a congenital abnormality (choanal atresia). Nasopharyngeal stenosis resulting from abnormally thickened palatopharyngeal muscles has also been reported in seven dachshunds (Kirkberger et al., 2006). Regardless of etiology, treatment aims are to establish patency of the choanae and nasopharynx and reduce the risk of restriction. Patency may be established by balloon dilation, bougienage, dilation using artery forceps, or surgical excision of the obstructing tissue. In some cases it may be possible to restore integrity of the nasopharyngeal mucosa by means of local flaps, but in most instances this is not feasible. Stents may be placed to maintain patency while epithelialization of the denuded area takes place, or

intermittent redilation may be performed (similar to the approach for esophageal strictures). Underlying conditions leading to the inflammation and mucosal ulceration must also be addressed to achieve long-term resolution of the nasopharyngeal obstruction.

Nasopharyngeal Cysts

Nasopharyngeal cysts may arise as a result of caudal nasal turbinate disease (in dogs) or cystic malformation of structures adjacent to the nasopharynx, such as the thyroglossal duct or Rathke's cleft. In cases of cystic Rathke's cleft, embryonic pituitary development proceeds abnormally, resulting in a progressively expansile cystic lesion within the sphenoid bone. Signs are often progressive and may not prompt an owner to seek veterinary attention until the patient reaches adulthood. Cystic Rathke's cleft may or may not be associated with pituitary dwarfism. Other types of developmental cysts have been encountered in dogs. A cystic or multilobulated appearance may also occur with cartilaginous and bony neoplasms of the skull such as multilobular osteosarcoma. Therefore histopathology is a very important component of diagnosis and surgical decision making. Cystic Rathke's cleft or other developmental bony cysts require surgical débridement and debulking. Simple cysts of the nasal turbinates may be removed by traction or flushing or may require surgical débridement.

Nasopharyngeal Neoplasia

Cats with nasal lymphosarcoma may, but do not always, have very long remission times after radiation therapy, multiagent chemotherapy, or both. Radiation protocols vary but usually result in the delivery of 3 to 5 Gy per fraction for a total of 6 to 10 fractions (total dose of 30 to 50 Gy). Although long remission times have been reported with radiation therapy alone, multiagent chemotherapy is usually recommended in combination to treat any systemic lymphosarcoma. In particular, renal lymphosarcoma has been noted as a sequel to successful radiation treatment for nasal lymphosarcoma. Debulking by nasal flushing or surgery may be required with nasopharyngeal lymphosarcoma for both diagnosis and immediate relief of respiratory obstruction.

Nasopharyngeal lymphosarcoma in dogs is exceedingly rare, and little information is available on its treatment. Treatment usually involves multiagent chemotherapy protocols with prior surgical debulking only if respiratory signs are severe.

Nonlymphoid nasal tumors that may involve the nasopharynx in dogs and cats include osteosarcoma, chondrosarcoma, fibrosarcoma, and carcinomas. A variety of treatments have been reported, including surgery, cryosurgery, radiotherapy, chemotherapy, and combinations of these. Orthovoltage radiation (with cytoreductive surgery) and megavoltage radiation both increase survival times in dogs. Orthovoltage radiation with cytoreductive

surgery resulted in statistically longer survival times than megavoltage radiation in one study (LaDue et al., 1999). Chemotherapy alone has traditionally demonstrated little efficacy in the treatment of nonlymphoid nasal tumors in dogs or cats. However, 81% of canine nasal tumors have been shown to express cyclooxygenase-2 (COX-2) (Kleiter et al, 2004), and a recent small case series demonstrated that the treatment with oral piroxicam (a COX-2 inhibitor) in conjunction with alternating doses of doxorubicin and carboplatin was efficacious and well tolerated (Langova et al., 2004). It is not known whether this protocol will be useful in nonlymphoid feline tumors, but it may offer a feasible alternative when radiation is unavailable.

Laryngeal Diseases

CATRIONA M. MACPHAIL, *Fort Collins, Colorado*

ERIC MONNET, *Fort Collins, Colorado*

The larynx is a term used to describe the cartilages that surround the rima glottis and that are responsible for control of airflow during respiration. The four cartilages that make up the larynx are the paired arytenoids and the unpaired epiglottis, cricoid, and thyroid cartilages. The cricoarytenoideus dorsalis muscle is solely responsible for opening the glottis. The muscle originates on the dorsolateral surface of the cricoid and inserts on the muscular process of the arytenoids. The recurrent laryngeal nerve innervates all of the intrinsic muscles of the larynx except the cricothyroid muscle. The function of the larynx is to regulate airflow, protect the lower airway from aspiration during swallowing, and to control phonation. Diseases most commonly affecting the larynx include laryngeal paralysis, laryngeal collapse, and laryngeal masses. All of these conditions result in some degree of upper airway obstruction. Dogs and cats typically present for respiratory stridor, voice change, coughing, or gagging. Progression of clinical signs is highly variable.

LARYNGEAL PARALYSIS

Etiology

Laryngeal paralysis is a common unilateral or bilateral respiratory disorder that primarily affects older large-breed dogs. However, a congenital form does occur in certain breeds such as Bouvier des Flandres, Siberian huskies, and Alaskan malamutes. Laryngeal paralysis-polyneuropathy complexes have been described in dalmatians and rottweilers. Acquired laryngeal paralysis is caused by damage to the recurrent laryngeal nerve or intrinsic laryngeal muscles from polyneuropathy, polymyopathy, trauma, or intrathoracic or extrathoracic masses. In most dogs the cause remains undetermined, and these cases are classified as idiopathic. The Labrador retriever is by far the most common breed reported; but golden retrievers, Saint Bernards, Newfoundlands, and Irish setters are also overrepresented.

Clinical Signs

Laryngeal paralysis results in the arytenoid cartilages and consequently the vocal folds remaining in a paramedian position during inspiration, in effect causing an upper airway obstruction. Dogs typically present with noisy inspiratory respiration and exercise intolerance. Early clinical signs include voice change and mild coughing and gagging. Severe airway obstruction results in respiratory distress, cyanosis, and collapse. Dogs may also present with signs of dysphagia. Progression of clinical signs is highly variable, and dogs may have clinical signs for several months to years

before significant respiratory distress ensues. However, clinical signs are easily exacerbated by heavy exercise or increasing environmental temperature. The majority of dogs present for surgical intervention in the late spring or early summer months (Snelling and Edwards, 2003). As respiratory rate increases, the arytenoids obstructing airflow may become inflamed and edematous, resulting in further airway obstruction. A vicious cycle ensues that if unaddressed may become life-threatening.

Diagnosis

Routine diagnostic evaluation for dogs thought to have laryngeal paralysis includes physical examination, complete blood count, biochemical profile, urinalysis, thyroid function screening, thoracic radiographs, and laryngeal examination. Dogs with bilateral laryngeal paralysis are at risk for aspiration pneumonia both before and after surgery. Therefore thoracic radiographs are a necessary part of the diagnostic workup in dogs suspected to have laryngeal dysfunction. For dogs that present with dysphagia or vomiting, an esophagram should be considered to rule out esophageal dysfunction or megaesophagus that may not be apparent on plain thoracic radiographs. Hypothyroidism is associated with laryngeal paralysis, although a direct link has yet to be established. Regardless, thyroid function screening is performed routinely in the workup for laryngeal paralysis. Thyroid supplementation should be instituted if indicated, although this does not typically improve clinical signs associated with laryngeal paralysis.

Definitive diagnosis of laryngeal paralysis requires visual examination of the larynx. However, laryngoscopy is a poorly specific diagnostic test since false-positives are common because of the influence of anesthetic agents on laryngeal function. Laryngeal paralysis should not be diagnosed solely on the lack of arytenoid movement. It can result in a fixed upper airway obstruction if there is secondary inflammation and swelling of the laryngeal cartilages. Diagnosis may also be confused by the presence of paradoxical movement of the arytenoids, resulting in a false-negative result. In this situation the arytenoid cartilages move inward during inspiration because of negative intraglottic pressure that is created by breathing against an obstruction. The cartilages then return to their original position during the expiratory phase, giving the impression of abduction. An assistant can state the stage of respiration during laryngoscopy to help distinguish normal from abnormal motion. Intravenous thiopental administered to effect is thought to be the best choice to allow for assessment of laryngeal function (Jackson et al., 2004). When a butorphanol-glycopyrrolate premedication

is used, either thiopental or propofol allows excellent visualization of the larynx (Gross et al., 2002). Doxapram HCl (1mg/kg intravenously [IV]) has been advocated for routine use during laryngoscopy to increase respiratory effort and intrinsic laryngeal motion and should be administered if the diagnosis is in doubt (Miller et al., 2002; Tobias, Jackson, and Harvey, 2004). Transnasal laryngoscopy to diagnose laryngeal paralysis using intramuscular sedation alone has been reported in a small number of dogs (Radlinsky, Mason, and Hodgson, 2004).

Emergency Treatment

For dogs that present in acute respiratory distress, initial treatment is directed at improving ventilation, reducing laryngeal edema, and minimizing the animal's stress. A typical treatment regimen involves oxygen supplementation and administration of short-acting steroids (e.g., dexamethasone 0.2 to 1 mg/kg IV) and sedatives (e.g., acepromazine 0.02 mg/kg IV). Additional administration of buprenorphine (0.005 mg/kg IV) or butorphanol (0.25 mg/kg IV) may also be considered. These dogs are also often hyperthermic, and appropriate cooling procedures should also be instituted. If respiratory distress cannot be abated, intubation or a temporary tracheostomy should be considered.

Conservative Treatment

Often dogs are not severely affected clinically until they have bilateral laryngeal paresis or paralysis. Therefore dogs with unilateral laryngeal dysfunction are not surgical candidates. For dogs with bilateral laryngeal paralysis, the decision to recommend surgery is based on the quality of life of the dog, severity of clinical signs, and time of year. Conservative management of dogs with laryngeal paralysis involves environmental changes, owner education, weight loss, and consideration of antiinflammatory drugs to minimize laryngeal swelling. For dogs that are diagnosed with concurrent hypothyroidism, thyroid supplementation should be instituted, but this rarely improves the clinical signs of laryngeal paralysis.

Surgical Treatment

Numerous surgical techniques are available to treat laryngeal paralysis. Unilateral arytenoid lateralization is the current technique of choice for most surgeons. Bilateral lateralization has been shown to result in unacceptable morbidity. Other techniques include partial laryngectomy, castellated laryngofissure, and permanent tracheostomy.

Several variations of unilateral arytenoid lateralization have been described. The most common technique involves suturing the cricoid cartilage to the muscular process of the arytenoid cartilage. This mimics the directional pull of the cricoarytenoid dorsalis muscle and rotates the arytenoid cartilage laterally. An alternative technique involves suture placement from the muscular process of the arytenoid cartilage to the caudodorsal aspect of the thyroid cartilage. This pulls the arytenoid cartilage laterally rather than rotating it and increases the area of the rima glottis to a lesser degree than the cricoarytenoid suture (Griffiths, Sullivan, and Reid, 2001). However, differences in techniques do not appear to affect postoperative outcome.

Partial laryngectomy consists of various techniques for vocal cord excision and partial arytenoidectomy to increase the diameter of the glottis. Partial laryngectomy has been associated with various complications, including laryngeal webbing, laryngeal scarring, and aspiration pneumonia. Complication rates as high as 58% have been reported (Harvey and O'Brien, 1982). However, bilateral vocal fold resection alone resulted in fewer complications and better postoperative outcome than other partial laryngectomy techniques (Holt and Harvey, 1994). This is thought to be to the result of better laryngeal protection during swallowing and decreased laryngeal irritation by leaving the corniculate processes of the arytenoid cartilages intact.

Prognosis

Postoperative aspiration pneumonia has been reported in 8% to 19% of dogs (MacPhail and Monnet, 2001; Snelling and Edwards, 2003; Hamonel, Hottinger, and Novo, 2006). Although aspiration pneumonia occurs most likely in the first few weeks following surgery, it has been recognized that these dogs are at risk for aspiration pneumonia for the rest of their lives. Factors that have been significantly associated with a higher risk of developing complications include preoperative aspiration pneumonia, postoperative megaesophagus, temporary tracheostomy placement, and concurrent neoplastic disease. Without surgical complications, unilateral arytenoid lateralization results in less respiratory distress and stridor and improved exercise tolerance. Owner satisfaction with this procedure has been reported as excellent, with the majority of owners believing that the quality of their dog's life was dramatically improved.

Laryngeal Paralysis in Cats

Laryngeal paralysis is an uncommon condition in the cat. Clinical presentation is similar to that of the dog, and both unilateral and bilateral laryngeal paralysis have been reported. Cats with unilateral laryngeal paralysis can present with significant clinical signs, unlike dogs that are rarely symptomatic. There also appears to be a prevalence of left-sided unilateral laryngeal paralysis in cats, which is similar to that reported in humans and horses. The specific etiology of laryngeal paralysis in cats is unknown, but several cases have been associated with trauma, neoplastic invasion, and iatrogenic damage. Neoplastic infiltration can lead to fixed laryngeal obstruction with both inspiratory and expiratory dyspnea and noise. Successful surgical treatment primarily using unilateral arytenoid lateralization has been reported (Scharchter and Norris, 2000).

LARYNGEAL COLLAPSE

Etiology

Laryngeal collapse is a secondary component of brachycephalic airway syndrome (see Chapter 141). Brachycephalic airway syndrome refers to the condition of airway distress attributable to anatomic abnormalities of breeds such as English bulldog and Boston terrier. Chronic

upper airway obstruction from the primary components of brachycephalic airway syndrome (stenotic nares, elongated soft palate) causes increased airway resistance and increased negative intraglottic luminal pressure. Over time this results in laryngeal collapse because of cartilage fatigue and degeneration. There are three stages of severity of laryngeal collapse. Stage 1 is the eversion of the laryngeal saccules into the glottis. The increased inspiratory effort creates a vacuum causing the mucosa of the laryngeal saccules to prolapse. In a retrospective study of dogs with brachycephalic airway syndrome, everted laryngeal saccules were present in almost 50% of affected dogs (Lorison, Bright, and White, 1997). The saccules are pulled from their crypts because of the high negative pressure within the glottis. Once the saccules are everted, the tissue is exposed to highly turbulent airflow, resulting in edema and inflammation, which further obstructs the airway. During stage 2 the cuneiform processes of the arytenoid cartilages lose rigidity and collapse into the laryngeal lumen. In addition, the aryepiglottic folds also collapse ventromedially. The most advanced phase of laryngeal collapse is stage 3 in which the corniculate process of each arytenoid cartilage fatigues and then collapses toward midline, resulting in complete laryngeal collapse.

Treatment

The early stage of laryngeal collapse is still amenable to surgical treatment. Resection of the everted laryngeal saccules is relatively simple. Each saccule is grasped with Allis tissue forceps and then sharply transected with Metzenbaum scissors. Suturing is not necessary. The difficulty of this technique lies in obtaining good visualization of the larynx and glottis. Often these dogs have redundant pharyngeal tissue that swells rapidly with minimal handling. The presence of an endotracheal tube can also make visualization difficult. It is for these reasons that some surgeons advocate using a temporary tracheostomy tube when performing this surgery. Stenotic nares and elongated soft palate should also be addressed if they have not been addressed previously.

Options for treatment of advanced stages of laryngeal collapse are limited. First, all other underlying conditions (stenotic nares, elongated soft palate, everted laryngeal saccules) are addressed. Unilateral arytenoid lateralization techniques are rarely successful since the opposite cartilage continues to collapse medially. Bilateral arytenoid lateralization techniques are considered unacceptable because of the high risk for aspiration pneumonia. Partial arytenoidectomy procedures have also been associated with a high rate of complications and perioperative mortality. Permanent tracheostomy is the recommended treatment for stage 3 laryngeal collapse, although many owners consider this an unacceptable option.

The most common way to perform permanent tracheostomy is to create a window in the ventral trachea encompassing 3 to 5 tracheal rings longitudinally and one third of the diameter transversely. Tracheal collapse can occur if the created stoma is too large. Ideally only the tracheal rings are removed, leaving the mucosa intact. An I-shaped incision is then made in the mucosa, and the edges are sutured directly to the skin using small monofilament nonabsorbable sutures

in a simple interrupted pattern. To minimize tension on the newly created stoma, some surgeons prefer to bring the trachea to a more superficial position by suturing the sternohyoideus muscles together dorsal to the trachea for the length of the proposed stoma.

The most significant complication associated with permanent tracheostomy comes from accumulation of mucus and secretions that may obstruct the trachea or stoma. Animals must be observed extremely closely in the first few days following surgery. Other complications include stricture of the stoma or occlusion of the stoma by excessive skinfolds. (See Chapter 141 for additional discussion of laryngeal collapse.)

LARYNGEAL MASSES

Neoplasia

Tumors of the larynx are uncommon in the dog and cat. Numerous types of tumor have been reported in the dog, including rhabdomyosarcoma, squamous cell carcinoma, adenocarcinoma, and mast cell tumor. Inflammatory nodules, especially involving the vocal folds, should be considered in the differential diagnosis. Squamous cell carcinoma and lymphoma are the most common tumors of the larynx in the cat.

Small lesions may be resected by partial laryngectomy. Aggressive surgical intervention involves complete laryngectomy with permanent tracheostomy but has only been reported in one dog. Radioresponsive tumors may be treated with radiation therapy. Otherwise most treatment is palliative, consisting of airflow bypass of the laryngeal area through permanent tracheostomy. Prognosis for laryngeal tumors is guarded because most cases are quite advanced at the time of diagnosis. There are only isolated reports of management of canine and feline laryngeal tumors (Jakubiak et al., 2005). Treatment of four cats with laryngeal squamous cell carcinoma with tube tracheostomy alone resulted in a median survival of only 3 days. Chemotherapeutic treatment of five cats with laryngeal masses resulted in a median survival of 141 days.

A recent study reported the placement of permanent tracheostomies in five cats with laryngeal carcinoma (Guenther-Yenke and Rozanski, 2007). Survival at home ranged from 2 to 281 days with two cats dying from tracheostomy site occlusion and three cats euthanized due to disease progression.

Benign Growths

Granulomatous laryngitis is an uncommon nonneoplastic proliferation of the arytenoid cartilages of the larynx that has been reported in both dogs and cats. Severe cases can result in laryngeal stenosis and significant upper airway obstruction. Mass biopsy is crucial to differentiate this disease from neoplasia. Treatment is palliative and consists of debulking of the mass, steroid therapy, or permanent tracheostomy.

Benign laryngeal cysts have also been described in isolated feline cases. Cysts are typically epithelial in origin and stem from the ventral aspect of the larynx. Surgical removal is usually curative. Some cysts are very large and can significantly obstruct airflow.

CHAPTER 144

Medical Management of Tracheal Collapse*

MICHAEL E. HERRTAGE, *Cambridge, United Kingdom*

Tracheal collapse is a syndrome characterized by dorsoventral flattening of the tracheal rings with laxity of the dorsal tracheal membrane. The syndrome is associated with clinical signs of cough and varying degrees of dyspnea and is most frequently encountered in middle-aged to old toy or miniature dogs. Considerable controversy surrounds the precise cause of the syndrome; consequently there is still little agreement concerning the most effective approach to its management. Much attention has been focused on refining methods for surgical reconstruction of the collapsed trachea, but it is by no means clear that all cases require or benefit from surgery.

Recently tracheal stenting has been advocated as a therapeutic procedure for tracheal collapse (see Chapter 145). A clearer understanding of the cause of the syndrome and the role played by the secondary factors that initiate the symptomatic state are probably the most urgent goals for future research.

ETIOLOGY

The cause of tracheal collapse is complex; it is best regarded as a syndrome with multifactorial causes, many of which are incompletely understood. The development of the clinical condition appears to require the presence of both a primary cartilage abnormality, resulting in weakness of the tracheal rings, and secondary factors capable of initiating progression to the symptomatic state.

*This chapter was originally published in *Current Veterinary Therapy XIII* and has been updated for this edition. The original chapter was co-authored by Richard A.S. White, FRCVS.

A reduction in the glycoprotein and glycosaminoglycan content of the hyaline cartilage of the tracheal rings is considered the primary defect responsible for the intrinsic weakness of the tracheal rings. This, together with other pathologic changes in the matrix, is responsible for reducing the capacity of the cartilage to retain water, consequently diminishing its functional rigidity (Dallman, McClure, and Brown, 1985). The evidence to suggest that these underlying abnormalities of the matrix have a congenital origin is compelling. Both the onset of clinical signs during puppyhood in some dogs and the presence of clinical signs in most symptomatic dogs long before middle age, when the disease is classically recognized, support this concept. Therefore it seems likely that affected dogs begin life with an abnormal trachea; and, conversely, dogs with normal tracheas are rarely susceptible to the disease.

Many toy and miniature dogs with the anatomic tendency to tracheal collapse can remain asymptomatic throughout life unless secondary or inciting factors initiate the clinical syndrome. These potential factors may include obesity, recent endotracheal intubation, respiratory infection, cardiomegaly, cervical trauma, and inhalation of irritants or allergens (Fig. 144-1). The precise role of upper airway obstruction in the etiology of the syndrome remains unclear. The presence of laryngeal paralysis or collapse in some affected dogs has led to the view that these conditions can precipitate the tracheal changes. Conversely, chronic obstructive disease of the lower airway is capable of promoting dynamic upper airway collapse; thus the interrelation of both conditions remains controversial.

The dynamic changes of tracheal collapse may be confined to either the cervical or thoracic region of the

trachea or may involve the entire length. Frequently the changes are most pronounced at the cervicothoracic junction. Collapse of the cervical tracheal segment occurs on inspiration because of the decreased pressure within the trachea, whereas the thoracic portion tends to collapse during the expiratory phase of respiration or during coughing as a consequence of increased intrathoracic pressure. In severely affected dogs these changes may also be detected more distally in the principal or proximal lobar bronchi. As a consequence of the flattened configuration of the tracheal rings, the dorsal membrane becomes widened, pendulous, and flaccid. The dorsal membrane contributes to the dynamic obstruction of the airway as it is drawn into the tracheal lumen during the respiratory cycle.

Once clinical signs are apparent, the syndrome is perpetuated by the cycle of chronic inflammation of the tracheal mucosa, which precipitates cough and in turn is exacerbated by the cough. Persistent inflammation of the tracheal mucosa leads to a loss of epithelium, fibrinous membrane formation, and squamous metaplasia with polypoid proliferation evident in advanced cases. The population of ciliated cells is reduced significantly by the metaplastic changes in the mucosa, and the hyperplastic subepithelial glands secrete increasingly viscid mucus. As a consequence, normal ciliary function is replaced progressively by cough as the major tracheobronchial clearing mechanism. Once the condition becomes symptomatic, the changes in the dorsal membrane and cartilage are believed to progress beyond those of the original anatomic abnormality; however, it has been difficult to document these worsening changes in individual cases.

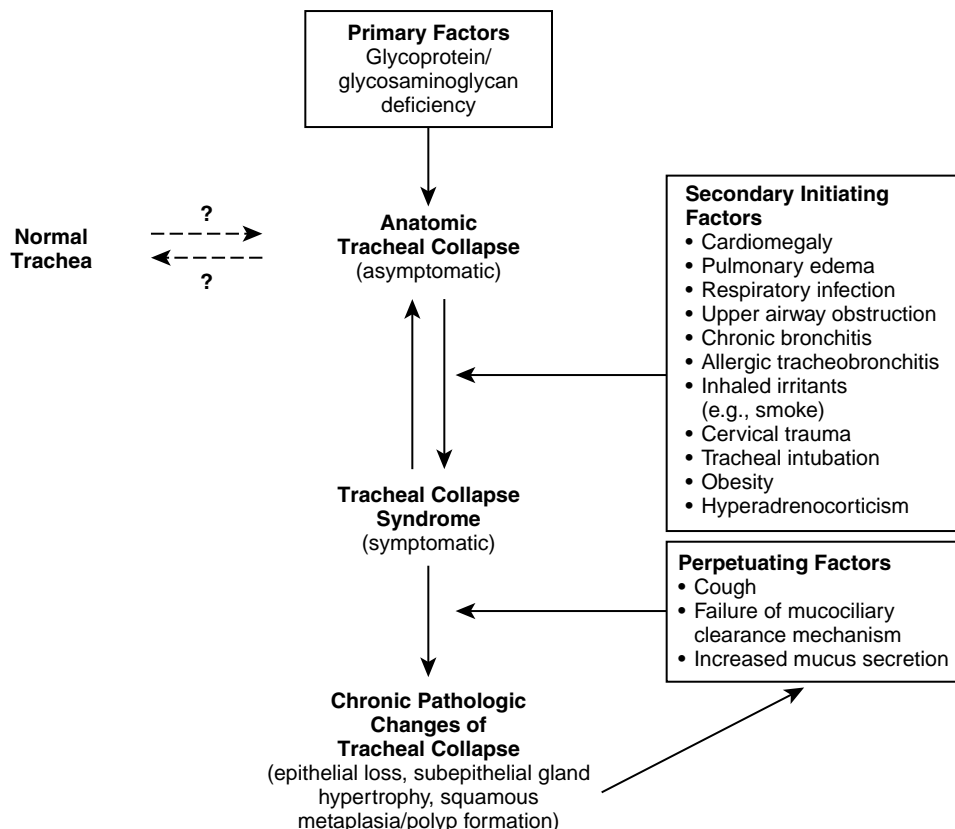

Fig. 144-1 Interrelation of probable factors involved in the etiology of tracheal collapse.

INCIDENCE

Tracheal collapse is confined almost exclusively to toy and miniature breeds and is only sporadically encountered in medium- to large-breed dogs. The Yorkshire terrier is the most commonly affected breed, but other commonly affected breeds include the miniature poodle, Chihuahua, and Pomeranian. Typically the patient is presented for evaluation at 6 to 7 years of age, although careful investigation usually reveals that signs referable to the condition have been present for some years before presentation. Approximately 25% of affected dogs are symptomatic by the age of 6 months. The syndrome is equally distributed between the sexes.

CLINICAL SIGNS

Tracheal collapse syndrome is characterized by a chronic, paroxysmal cough precipitated by excitement, anxiety, or pulling on the leash. The cough is typically harsh, dry, and nonproductive and is easily elicited on tracheal palpation. A “goose honk” cough is a frequent but not consistent finding. Affected dogs may be otherwise asymptomatic and are often able to sustain prolonged periods of exercise without any clinical signs. However, more severely affected dogs may show varying degrees of tachypnea or even respiratory distress as a result of the severity of airway obstruction. Cyanosis or syncope from hypoxemia may be noted in advanced cases. The severity of clinical signs does not relate directly to the severity of the anatomic changes, and classification systems describing the degree of tracheal collapse are of limited help in this respect.

On physical examination turbulent air flow may be detected on auscultation directly over the cervical trachea, whereas referred musical or wheezing sounds may be heard on thoracic auscultation. The lung sounds in tracheal collapse may be normal or accentuated; however, in many cases bronchovesicular sounds are obliterated by referred sounds from the trachea. In dogs with tracheal collapse the heart rate is usually normal or slow at rest with pronounced sinus arrhythmia, whereas dogs with left ventricular heart failure often lose sinus arrhythmia because of increased sympathetic tone, and the heart rate is often increased. The cough in left ventricular heart failure is typically soft, moist, and mildly productive compared with the harsh, dry cough of tracheal collapse; however, left atrial enlargement can also cause left bronchial compression, which can mimic signs of tracheal collapse. Some dogs with tracheal collapse acquire pulmonary hypertension, which may result in a prominent or split second heart sound.

DIAGNOSIS

Confirmation of the diagnosis of tracheal collapse syndrome requires the combination of a persistent cough, a response to tracheal palpation, and demonstration of intratracheal changes, preferably by endoscopy. The dynamic dysfunction of the trachea can be demonstrated by a variety of diagnostic methods, including palpation, radiography, ultrasonography, or tracheoscopy.

Physical Examination

Collapse of the cervical portion of the trachea is usually readily appreciated on physical examination by careful palpation. The tendency of the dorsal membrane to invert into the tracheal lumen can be appreciated by gentle digital pressure once the trachea has been rolled laterally. More significantly, in affected dogs this maneuver usually initiates a cough.

Radiographic Examination

Radiography can be useful in demonstrating dynamic tracheal collapse during the different phases of the respiratory cycle. The most useful radiographic examinations include lateral projections of the thoracic inlet exposed during the inspiratory and expiratory phases, a tangential rostro-caudal (skyline) projection of the thoracic inlet, and fluoroscopic investigation to demonstrate movement of the dorsal membrane during the respiratory cycle. Luminal narrowing of the cervical trachea is seen on the lateral projection during inspiration, whereas ballooning of the same segment may be seen on expiration. These changes may be visible during expiration for the thoracic segment. These dynamic changes, including “fluttering” of the dorsal membrane during the respiratory cycle, are best viewed in real time using image-intensified fluoroscopy since radiographs tend to underestimate the frequency and degree of tracheal collapse (Macready et al., 2007). In the skyline projection the flattened trachea is seen as an oval, C, or crescent shape. In severe cases the cross section of the trachea at the thoracic inlet may be narrowed to a slitlike opening. Coughing in such cases may create the appearance of a highly redundant segment of trachea at the thoracic inlet. It should be emphasized that radiography may not highlight the dynamic changes of collapse in all cases.

Ultrasonography

Like fluoroscopy, ultrasonography provides real-time imaging that can be used to demonstrate dynamic changes in the tracheal profile. The technique has the distinct advantages of being noninvasive and safe and can be performed on minimally sedated or unsedated animals (Rudorf, Herrtage, and White, 1997). A high-frequency transducer with a standoff is required for imaging of the larynx and trachea. The transducer is positioned ventrally over the trachea just caudal to the cricoid cartilage; with the neck in a neutral position, a transverse scan is made of the air shadow between the cricoid and first tracheal ring. Beginning from this point, the transducer is moved caudally, imaging the profile of the tracheal air shadow during the phases of the respiratory cycle and during hyperextension of the neck. Interpretation requires some experience.

Endoscopy

Tracheoscopic examination of the tracheal lumen should be regarded as the gold standard for the purposes of completing a diagnosis. Tracheoscopy is useful to confirm not only the presence of the anatomic abnormality but also changes in the dorsal membrane along its entire

length. The ventrodorsal movement of the dorsal membrane during the respiratory cycle can be appreciated in lightly anesthetized dogs. In some dogs with severe obstruction there may be an increased anesthesia risk, but this rarely proves to be a problem.

Microbiologic and Cytologic Studies

Tracheoscopy also permits the recovery of bacteriologic and cytologic samples from the lower respiratory system. Samples should be cultured for bacterial isolation and sensitivity, and cytologic studies should be performed to identify any cellular changes suggestive of an inhaled allergic or inflammatory airway response (see Chapter 146).

Other Tests

The identification of specific allergens or irritants often is not practical, although removal of the dog from cigarette smoke in the environment for a test period is often useful in investigating this as a common initiating cause.

Significant hepatic dysfunction is identified in many dogs with tracheal collapse (Bowes et al., 2006). Therefore liver function testing should be performed in cases of tracheal collapse, especially those with severe respiratory signs.

THERAPY

The clinician must be prepared to pursue several therapeutic avenues in the management of the individual dog to deal with the complex and multifactorial etiology of the syndrome (White and Williams, 1994). Since anatomic collapse alone does not guarantee a symptomatic state, every effort should be made to identify and correct any secondary causes. Successful long-term medical management is possible for the majority of patients provided the initiating factor or factors can be identified. This route should always be thoroughly investigated before a surgical solution is considered.

The Acute Case

The dog presenting in acute respiratory distress should be regarded as a medical emergency, and all diagnostic tests should be postponed until the dog has been stabilized. The dog should be sedated as required and subjected to as little stress as possible. Acepromazine (ProMACE, Fort Dodge) at a dose of 0.02 to 0.2 mg/kg intravenously, intramuscularly, or subcutaneously is generally effective. Oxygen therapy administered via a face mask may be the most practical means of improving the patient's oxygen status initially, but nasal intubation often causes the patient less anxiety for long-term management. We have used tracheostomy intubation as a temporary means of establishing an airway in hyperexcited dogs with severe obstruction with seemingly few long-term complications. In some dogs the tachypnea may promote hyperthermia, exacerbating the dyspnea. The dog should be kept in a cool environment or ice packs applied in severe cases to counter this problem. Short-acting glucocorticoids (e.g., dexamethasone sodium phosphate [Azium SP, Schering-Plough]) given once at a dose of 1 mg/kg intravenously

may be helpful for dogs with laryngeal edema or tracheal inflammation. Opioid agonist-antagonists such as butorphanol (Torbutrol, Fort Dodge) at a dosage of 0.05 to 0.11 mg/kg every 6 to 12 hours intravenously, intramuscularly, or subcutaneously or buprenorphine hydrochloride (Buprenex, Reckitt and Colman) at a dosage of 0.01 to 0.02 mg/kg every 12 hours intramuscularly are useful mild cough suppressants that cause little respiratory depression. When either of these drugs is combined with acepromazine, the resultant sedation can be significant.

Management of Secondary Initiating Causes

Weight Reduction

Many dogs with tracheal collapse are obese, and their intrathoracic adipose deposits may interfere with respiratory excursion, causing a reduction in thoracic wall compliance. Weight reduction should be pursued aggressively in all overweight patients to improve respiratory function; the clinical response can be dramatic in some cases. The daily caloric intake should be based on a high-fiber, low-calorie diet and restricted to 60% of the total daily requirement based on a lean body mass. Exercise restriction may limit the rate of weight loss. The veterinarian should monitor progress and encourage owner compliance with the regimen.

Congestive Heart Failure

Heart failure with pulmonary edema may initiate or exacerbate the clinical signs of tracheal collapse by increasing the volume of tracheobronchial secretions. In addition, the cough may be promoted by pressure of the enlarged left atrium on the left main-stem bronchus. Reduction of preload by diuresis and the use of angiotensin-converting enzyme inhibitors reduce pulmonary edema. Digitalization or administration of pimobendan may also be effective in suppressing the cough associated with congestive heart failure (see Chapter 171).

Inhaled Irritants

In some dogs the clinical syndrome of collapse may be precipitated by the inhalation of irritants or allergens. The removal of cigarette smoke from the dog's environment is an essential, although often difficult, part of the management regimen. The recognition and removal of other inhaled allergens is less straightforward but may prove beneficial in some dogs.

Respiratory Infections

Infections of the lower respiratory tract should be treated by appropriate antibacterial therapy optimally based on the results of bacterial culture from bronchoalveolar lavage. Treatment should be continued for a minimum of 14 days and in selected cases may need to be continued for prolonged periods for the control of deep-seated chronic infection. When antimicrobial therapy is initiated empirically, without microbiologic or cytologic confirmation of infection, doxycycline, cephalixin, or amoxicillin-clavulanate are common antibiotic choices.

Collars

The use of collars, particularly of a sliding chain design, should be discouraged because repeated external pressure

on the trachea may initiate mucosal irritation and promote coughing. Body harnesses are an alternative, although these may still pose some risk.

Management of the Coughing Animal

Antitussive Agents

Cough suppressants are recommended to reduce chronic irritation or damage to the tracheal epithelium caused by collapse of the dorsal membrane and to reduce shearing forces within the lung associated with chronic coughing. A variety of drugs are available, but we have had greatest success using co-phenotrope (Lomotil, Searle), which contains diphenoxylate hydrochloride and atropine.* The diphenoxylate acts as a narcotic antitussive agent, and the atropine reduces the volume of mucus secreted into the lower respiratory tract and also acts as an anti-muscarinic bronchodilator. The recommended dosage of co-phenotrope is 0.2 to 0.5 mg of diphenoxylate per kilogram orally every 12 hours; this dosage can be maintained for extended periods until clinical signs subside. Constipation is an occasional problem but usually can be controlled by adding a stool softener to the diet. Other narcotic antitussive agents such as hydrocodone (Russigan, Daniels Pharmaceuticals; 0.22 mg/kg orally [PO] every 6 to 12 hours), codeine phosphate (Bronlex, Procter and Gamble Pharmaceuticals; 0.5 to 2.0 mg/kg PO every 12 hours) or butorphanol (Torbutrol, Fort Dodge; 0.5 to 1 mg/kg PO every 6 to 12 hours) may be used but are generally less effective than co-phenotrope.

Bronchodilators

The use of bronchodilators in the management of tracheal collapse is regarded as controversial by some authors. The rationale for their use is based on the dilation of pulmonary airways, which decreases intrathoracic pressure during expiration, thereby decreasing the tendency to tracheal narrowing during expiration. Use of bronchodilators is particularly important for patients with coexisting small airway disease with increased intrathoracic pressure on expiration and thus a greater tendency to tracheal collapse. Methylxanthine bronchodilators (theophylline) may be beneficial in achieving bronchodilation, improving mucociliary clearance, and reducing diaphragmatic fatigue in dogs with tracheal collapse. The preparations most commonly used include sustained-release theophylline (Theo-dur, Key Pharmaceuticals) at a dosage of 10 to 20 mg/kg orally every 12 hours and theophylline ethylenediamine (aminophylline, Roxane and Alparma) at a dosage of 8 to 10 mg/kg orally every 8 hours. Older dogs often demonstrate apparent anxiety and restlessness when full doses of theophylline are administered, and clients should be warned to report any adverse drug effects.

β_2 -Adrenergic agonists also can be used for bronchodilation. Terbutaline (Brethine, Ciba Geneva; 1.25 to 5 mg/

dog PO every 8 to 12 hours) and albuterol (Proventil, Schering; Ventolin, Glaxo-Wellcome; 50 mcg/kg PO every 8 hours) have been recommended for use in dogs. Signs of β -agonist toxicity include hypotension and tachycardia, and these could be reduced by inhalation administration. Care should be taken when using these drugs in dogs with congestive heart failure.

Glucocorticoids

Glucocorticoids should be used judiciously in the management of tracheal collapse. Drugs in this class may be beneficial in reducing laryngeal, tracheal, or bronchial inflammation but should be used for short periods only because their extended use may exacerbate bacterial infections, promote tachypnea, or cause iatrogenic hyperadrenocorticism. Glucocorticoids also promote weight gain and may make weight reduction difficult to achieve. Prednisolone (Prednistab, Vedco) may be used initially at a dosage of 0.5 mg/kg orally every 12 hours. Since the benefits of glucocorticoids are normally apparent within 7 to 10 days, the dosage should be tapered and withdrawn within this period. Inhaled corticosteroids may be used to reduce side effects of glucocorticoid administration (Bexfield et al., 2006).

Surgical Management

Surgical or device management of tracheal collapse is appropriate for dogs that remain persistently symptomatic despite vigorous medical management and attempts to eradicate all potential initiating factors. Candidates for reconstruction of the trachea should be selected carefully and should be free of other medical complications, including congestive heart failure and collapse of the lower airway, because these dogs rarely improve with surgical intervention.

A variety of surgical techniques have been described for the management of tracheal collapse. Most of these techniques, including tracheal ring chondrotomy, plication of the dorsal membrane, prosthetic mesh support, and intraluminal prosthetic supports, have little foundation in success and are no longer considered to be practical. Placement of external prosthetic supports currently is the preferred technique for surgical management of tracheal collapse, and both ring (Hobson, 1976) and spiral (Fingland, DeHoff, and Birchard, 1986) prostheses manufactured from polypropylene are used. Most authors suggest reconstruction of the cervical and, when affected, the thoracic segment. However, the results of surgical management of the thoracic portion of the trachea are frequently unrewarding because of the high morbidity associated with this procedure. A number of complications have been associated with implantation of prosthetic tracheal supports, including loosening or failure of the implant, infection, laryngeal paralysis, and tracheal necrosis. Isolation of the tracheal blood supply to accommodate the application of prostheses has been demonstrated to result in significant impairment of the tracheal blood flow, risking necrosis (Kirby et al., 1991). However, a modified dissection of the lateral pedicles permits preservation of the vascular supply to one side of the trachea and avoids serious ischemic complications (Coyne et al., 1993). Arytenoid lateralization at the time of surgical reconstruction of the trachea may improve

*Co-phenotrope (diphenoxylate hydrochloride with atropine) is not in widespread use as an antitussive agent in the United States, and no clinical trials demonstrating its efficacy and safety for this indication have been published. The potential adverse effects of atropine on the viscosity of airway secretions warrant further investigation.

the results of surgery (White, 1995). The prognosis for older dogs (>6 years of age at the time of surgery) is significantly worse than that for younger dogs, even though the degree of tracheal collapse, as assessed by tracheoscopy, may be less severe (Buback, Boothe, and Hobson, 1996). As emphasized previously, the severity of the grade of collapse does not appear to have any prognostic significance.

More recently intraluminal stent implantation has been used to treat dogs with severe tracheal collapse; this technique and its complications are discussed in Chapter 145.

CHAPTER 145

Intraluminal Stenting for Tracheal Collapse

CHICK W.C. WEISSE, *Philadelphia, Pennsylvania*

Tracheal collapse is a progressive degenerative disease of the cartilage rings in which hypocellularity and decreased glycosaminoglycan and calcium contents lead to dynamic airway collapse during respiration. This is a condition of predominantly small- and toy-breed dogs that can present with signs ranging from a mild, intermittent “honking” cough to severe respiratory distress from dynamic upper-airway obstruction. Although more commonly seen in older patients, dogs of all ages can be affected. Many of these patients are palliated first by conservative therapies, including general management strategies and medications (see Chapter 144). Weight loss, restricted exercise, and removal of second-hand smoke or inhaled allergens can reduce clinical

signs. In addition, management of comorbidities such as cardiac disease or bronchopulmonary disease can help reduce the frequency of respiratory crisis episodes. These conditions, especially chronic bronchitis (see Chapter 146), should be sought and managed. Conservative treatment combinations used in dogs with tracheal collapse include antiinflammatory drugs, antitussives, sedatives/tranquilizers, or bronchodilators. These therapies, which are discussed in the previous chapter, may reduce the respiratory signs associated with tracheal collapse. The dog that has been evaluated comprehensively for other causes of cough and has failed aggressive conservative management for tracheal collapse is a candidate for surgical or interventional treatment.

The most commonly performed surgical treatment for patients with extrathoracic tracheal collapse is extraluminal polypropylene ring prostheses. This technique involves placing extraluminal support rings around the trachea during an open cervical approach and has a reported 75% to 85% overall success rate for reducing clinical signs in one report of 90 dogs (Buback, Boothe, and Hobson, 1996). However, this procedure is not without complications since 5% of animals died perioperatively, 11% developed laryngeal paralysis from the surgery, 19% required permanent tracheostomies (half within 24 hours), and \approx 23% died of respiratory problems with a median survival of 25 months. In addition, only 11% of the dogs in this study had intrathoracic tracheal collapse (all dogs had extrathoracic tracheal collapse). The authors advised against this technique in patients with intrathoracic tracheal collapse because the resulting morbidity was unacceptably high.

The combination of surgical risk and the inability to adequately treat intrathoracic collapse led to the evaluation of human-intended, intraluminal tracheal stents for dogs with tracheal collapse. A number of stents have previously been evaluated in the canine trachea, including both balloon-expandable (Palmaz), and self-expanding (stainless steel, laser-cut nitinol, knitted nitinol) stents (Radlinsky et al., 1997; Norris et al., 2000; Moritz, Schneider, and Bauer, 2004). Clinical improvement rates in 75% to 90% of dogs treated with intraluminal, stainless steel, self-expanding metallic stents (SEMSs) have been reported (Norris et al., 2000; Moritz, Schneider, and Bauer, 2004). Immediate complications typically were minor, although there was a perioperative mortality rate of approximately 10%. Late complications included stent shortening, excessive granulation tissue formation, progressive tracheal collapse, and stent fracture. Some of these can be severe or life-threatening.

Neither surgery nor stenting is a cure for tracheal collapse. However, when used appropriately in the proper patient, both can improve the patient's quality of life significantly when medication alone is no longer adequate. My criteria for patient selection, method of stent selection, and technique for placing intraluminal tracheal stents follow.

PATIENT SELECTION AND EVALUATION

The diagnosis of tracheal collapse and other forms of respiratory dysfunction is beyond the scope of this chapter, but important rule-outs for chronic or recurrent coughing include chronic bronchitis, pneumonia, congestive heart failure, heartworm disease, and pulmonary neoplasia. Since comorbid disorders can complicate or even dominate the signs related to tracheal collapse, other primary or secondary respiratory disorders must be considered and managed before more invasive therapies for tracheal collapse. Animals with concurrent cardiac or bronchopulmonary disease can often benefit substantially from medical treatment such that invasive tracheal collapse treatments can be avoided or postponed.

Whether considering surgical rings or intraluminal stenting, it is important that aggressive medical management has been attempted and failed at providing a reasonable quality

of life for the patient (see previous chapter). Although it is a subjective criterion, the veterinarian and owners must carefully evaluate the patient's status and agree when the time for more aggressive therapy is indicated. An exception to this rule is the emergent, intubated patient that has failed a number of attempts at extubation. It should be emphasized that an owner's inability to administer medication is not a valid reason to perform any invasive procedure for tracheal collapse since the majority of dogs will still require long-term medication.

RINGS OR STENT?

The decision to perform surgery versus stenting is complicated, and the best approach is still unresolved. Decisions must be made on an individual basis, but some guidelines can be advanced. In my opinion, if significant *intrathoracic* tracheal collapse is present, surgery is either unlikely to resolve the problem or will be associated with unacceptable morbidity; therefore an intraluminal stent should be considered in these cases. If only cervical tracheal collapse is present, surgical rings should be considered. An exception may be in a geriatric patient or one with cardiorespiratory or endocrine comorbidities that might make prolonged anesthesia or wound healing more of a concern.

The patient with extensive intrathoracic and extrathoracic tracheal collapse presents an even more complicated scenario. It can be argued that an intraluminal stent for the intrathoracic collapse and surgical rings for cervical collapse might avoid some of the complications associated with very long tracheal stents; however, the alternative view is that this approach would combine the potential complications associated with both procedures. In these cases I am currently placing a single long stent to span both the intrathoracic and extrathoracic trachea.

MAIN-STEM BRONCHIAL COLLAPSE

Much debate remains concerning the use of intraluminal stents in patients with main-stem bronchial collapse. Unfortunately no data are available to recommend or oppose the routine use of intraluminal stents in these patients; therefore one can only offer a personal opinion. The questions raised are twofold.

First, should stents be placed *within* collapsing main-stem bronchi? Currently I do not recommend stenting of collapsing main-stem bronchi routinely. Placing stents in main-stem bronchi will "cage-off" other bronchi and consequently prevent drainage from the associated lobes. In addition, secondary and tertiary bronchi will continue to collapse; therefore the benefit achieved from the bronchial stenting will likely be minimal and temporary when compared to the risks.

Second, should tracheal stents be placed in patients with main-stem bronchial collapse? Certain patients benefit from tracheal stenting, even with concurrent main-stem bronchial collapse. The patient should be carefully evaluated by fluoroscopy and endoscopy to determine the primary disorder. Tracheal collapse can lead to dyspnea, persistent cough, or both. If dyspnea is the major

clinical sign and intrathoracic tracheal collapse is present, a tracheal stent can help relieve the dynamic obstruction. If the patient's primary problem is coughing, it becomes difficult to determine if the coughing is the result of the tracheal collapse, bronchial collapse, or another problem such as chronic bronchitis. In these patients I always warn the owner that continued coughing will likely be present after stenting because the main-stem bronchial collapse (as well as collapse of the smaller bronchi) will continue. In addition, in my experience continued, intractable coughing causes repeated cycling of the stent, increasing the risk of device fracture or formation of excessive granulation tissue. Persistent coughing must be treated aggressively to minimize the risk of these complications.

EXPECTATIONS/RISKS: DISCUSSION WITH OWNER

Once the decision has been made to consider tracheal stenting, an in-depth discussion with the owner reviewing all of the risks should take place. Neither surgery nor stenting has been demonstrated to slow the progression of disease, and both techniques are considered palliative. As indicated previously, clinical improvement rates of 75% to 90% were reported with intraluminal SEMSs (Norris et al., 2000; Moritz, Schneider, and Bauer, 2004). Most periprocedure complications were minor; however, in 10% of the dogs serious complications resulted in death. Late complications must be discussed with the owner, including stent shortening, excessive granulation tissue formation, progressive tracheal collapse, and stent fracture. Continued coughing should be expected in any dog with concurrent bronchial collapse, and these patients may carry a worse prognosis. In addition, the vast majority of dogs require continued medical therapy.

STENT PROPERTIES

A general review of stents is beyond the scope of this chapter; however, a brief discussion of certain stent characteristics will aid the reader in understanding the options available to the operator. The SEMS is used almost exclusively to treat tracheal collapse in dogs. (Balloon-expandable metallic stents are used rarely and are not discussed in this chapter). SEMSs are expanded to their stated measurements in the resting phase. Following manufacturing, the SEMSs are collapsed using a number of different techniques and loaded onto a delivery system covered by a sheath, which allows introduction through very small holes such as a vascular sheath or endotracheal (ET) tube. Following placement, the stent is deployed by retracting the surrounding sheath, allowing the stent to expand back to its original size and shape.

Stent Material

The majority of stents manufactured today are made of nitinol, which is classified as a shape-memory metal. The material is an alloy of nickel (Ni) and titanium (Ti) alloy developed by the Naval Ordnance Laboratory. Laser-cut nitinol stents are cut from hollow tubes of nitinol under extreme temperatures, altering the properties of

Fig. 145-1 **A**, Mesh nitinol stent (Vet Stent-Trachea, Infiniti Medical). Note the rounded edges of this stent chosen to reduce potential granulation tissue development. **B**, Mesh stainless steel stent (Courtesy Wallstent, Boston Scientific).

the metal and allowing compression of the stent onto a delivery system. On returning to ambient temperature, the stent favors its original design, which is achieved following release from the delivery system and sheath. Laser-cut nitinol SEMSs currently are not recommended for the treatment of tracheal collapse in veterinary patients because of an unacceptably high occurrence of stent fracture (personal experience). Woven, knitted, or mesh stents are designed to be compressed onto a delivery system at normal temperatures through design modifications. Examples of more commonly used nitinol stents in veterinary patients currently include mesh stents (Vet Stent-Trachea, Infiniti Medical)* or knitted stents (Ultraflex, Boston Scientific). Other commercially available stents used for tracheal collapse are made of stainless steel or similar alloys (Wallstent, Boston Scientific) (Fig. 145-1).

Foreshortening

The majority of stents currently placed for tracheal collapse in veterinary medicine are mesh or knitted SEMSs and undergo some degree of “foreshortening.” This term refers to the shortening of the stent that is encountered as it is released from the delivery system. As indicated on the packaging, the stent size refers to the diameter and length at full expansion. If the stent does not achieve full expansion (i.e., the lumen in which it is placed prevents complete expansion to its original diameter), the stent will be *longer* than expected. In other words, the stents are significantly longer when viewed on the delivery system. As the stent expands it shortens, and as such the ultimate length of the stent is inversely proportional to the degree of expansion (the less the stent expands, the longer it will remain). This extremely important property of knitted and mesh stents

*The author is a consultant for Infiniti Medical, LLC and has been involved in the specifications chosen for the Vet Stent-Trachea and Delivery System.

must be recognized and accounted for during the stent selection process. For example, stent diameters of 10% to 15% greater than the diameter of the trachea are commonly chosen for tracheal stenting. The more oversized the stent, the longer the stent following initial deployment, and the greater the tendency for the stent to shorten over time (as it expands to its original diameter). This gradual shortening must be accounted for when choosing the appropriate stent length. An oversized stent may need to cover additional segments of normal trachea beyond the extremes of the collapse because future stent shortening should be anticipated. Typically the cranial end of the stent shortens in a caudal direction over time, most likely related to the larger diameter of the cervical trachea when compared to that of the intrathoracic trachea. When collapse extends to the larynx, the stent is placed to extend as far cranially as possible without contacting the cricoid cartilage. If the oversized stent gradually shortens over time, a single extraluminal ring can be placed surgically if clinical signs redevelop.

Stent Sizing

To choose an appropriately sized stent, it is important to determine the length of the collapse and the diameter of the trachea. The stent length and diameter are based on these metrics.

Stent Length

I prefer to identify the length of collapse in the awake animal using fluoroscopy. Although tracheoscopy historically has been regarded as the gold standard for identifying tracheal collapse, this procedure requires general anesthesia, which can add significant risk in these often debilitated patients. Simple radiography is not adequate for identifying the length of collapse because different areas of collapse are apparent during different phases of respiration (Fig. 145-2). I prefer to perform fluoroscopy in the fully awake dog. In addition, it is important to induce coughing if possible since these extreme airway pressures often reveal more extensive collapse than that identified during more relaxed breathing (Fig. 145-3). Anatomic landmarks are then identified to record the cranial-most and caudal-most extent of the collapse.

Occasionally a patient presents that is unable to be extubated following general anesthesia for an unrelated procedure. Under these circumstances the technique described previously is not possible. For these cases I use a homemade negative-pressure ventilation device (Fig. 145-4). Following preoxygenation with a series of positive-pressure ventilations, this apparatus is connected to the ET tube, and the dosing syringe plunger is withdrawn to -10 to -15 cm H₂O on the sphygmomanometer as a radiograph is taken to document the location of collapse (Fig. 145-5).

Fig. 145-2 Inspiratory and expiratory radiographs of the same dog demonstrating cervical tracheal collapse most apparent during inspiration (*top image*) and intrathoracic tracheal collapse most apparent during expiration (*bottom image*).

Fig. 145-3 Fluoroscopic images demonstrating dramatic difference in identification of length of tracheal collapse present during passive respiration (*top image with thoracic inlet tracheal collapse*) and a coughing episode (*bottom image*). Note the extensive collapse and apparent folding of the caudal cervical trachea that occurs during coughing.

Fig. 145-4 Negative-pressure ventilation device attached to the endotracheal tube and used to identify the length of tracheal collapse in an anesthetized dog.

Fig. 145-5 Serial fluoroscopic images of the same dog under normal resting respiration, negative-pressure ventilation (NPV), and positive-pressure ventilation (PPV). Note the extensive tracheal collapse apparent under NPV; it is less clear under resting respiration. Under PPV dilation of the entire trachea is apparent.

Once the length of the collapse has been determined, the stent length is typically chosen to extend at *least 1 cm beyond the cranial and caudal extents of collapse*. If the entire length of the trachea is affected, the stent length is usually chosen to extend from approximately 1 cm cranial to the carina to 1 cm caudal to the cricoid cartilage of the

larynx. For shorter lengths of collapse, one must decide whether the animal will benefit from complete tracheal stenting versus covering a shorter segment. One study identified a potential increased risk of complications in animals receiving longer Wallstents; however, this finding was not corroborated in another study (Norris et al., 2000; Moritz, Schneider, and Bauer, 2004). A correlation between stent length and complication rate has not been apparent in my experience; and, if progression of tracheal disease is expected, the patient generally receives stenting across most of the tracheal length.

Stent Diameter

Typically the tracheal diameter is determined at the time of stent placement to prevent having to repeat general anesthesia. I place a measuring catheter within the esophagus to account for radiographic magnification (described later in the paragraph). Alternatively some other measuring device can be placed externally and included in the radiograph. The ET tube is withdrawn until the cuff is just caudal to the larynx. Positive-pressure ventilation of 20 cm H₂O is temporarily performed to achieve maximal tracheal expansion, and a radiograph is taken. The radiopaque marks on the marker catheter are 10 mm apart; this distance is measured on the radiograph and is also used to account for radiographic magnification. This extrapolation (known distance between markers plus magnification) is used to determine the actual maximal diameters of the intrathoracic and cervical tracheas (Fig. 145-6). The stent diameter chosen is usually $\approx 10\%$ to 20% greater than the maximal tracheal diameter to minimize chances of stent migration. I generally inventory stents in 2-mm diameter increments (i.e., 8-mm, 10-mm, 12-mm, and 14-mm diameter). The cervical trachea is routinely larger in diameter than the intrathoracic trachea; however, the difference in these two measurements can vary dramatically. When the two diameters are similar (within 2 mm), the stent diameter chosen is equal to the maximal tracheal diameter or no more than 10% to 20% larger than the maximal diameter. For example, a dog with a maximal intrathoracic diameter of 8 mm and a maximal cervical tracheal diameter of 10 mm would likely receive a 12-mm diameter stent. When the tracheal diameter discrepancy is greater than 2 mm, stent sizing is more difficult. The risks of undersizing stent diameter are apparent (mucus trapping and stent migration); however, the risk of oversizing stent diameter is theoretical at this time (mucosal damage, excessive granulation, increased coughing). Therefore, one must consider the options: (1) Increase stent diameter by 10%-20% of largest tracheal diameter; (2) place two tracheal stents of different diameter; or (3) place cervical rings and intrathoracic tracheal stent. All of these options are reasonable and have been performed.

STENT PLACEMENT TECHNIQUE

The following description applies to placement of mesh SEMSs (Vet Stents–Trachea, Wallstents). Key issues include anesthesia and patient preparation, the specific procedural steps needed for successful stent deployment, and patient follow-up and aftercare.

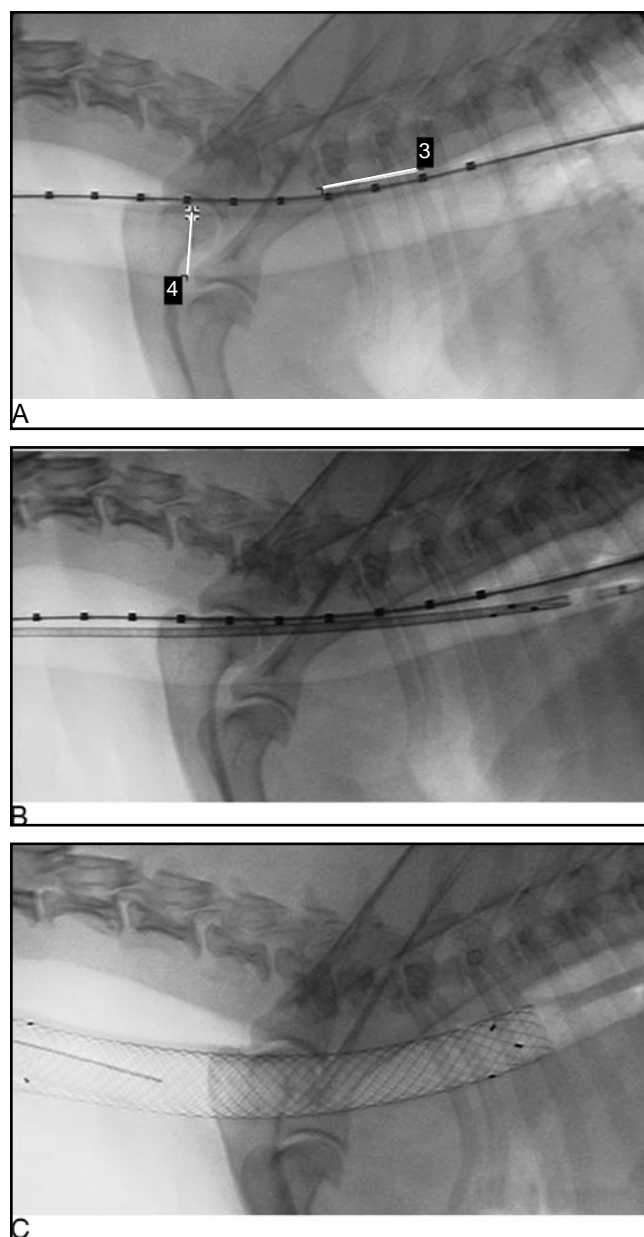

Fig. 145-6 Serial fluoroscopic images during tracheal sizing and stent placement. **A**, Using positive-pressure ventilation and an esophageal marker catheter, measurements are taken to determine the maximal tracheal diameter. **B**, The stent delivery system is advanced into the trachea. Note that the cervical and intrathoracic trachea are in line to facilitate passage of the stent. **C**, Restoration of a patent trachea immediately following placement of an intraluminal tracheal stent.

GENERAL ANESTHESIA AND PATIENT PREPARATION

Anesthesia protocols differ among institutions; however, I prefer a rapid induction and recovery. Premedication is routinely avoided unless intravenous catheterization creates excessive anxiety and respiratory distress. When necessary, an antitussive/tranquilization combination such as butorphanol (0.2 to 0.3 mg/kg intramuscularly [IM]) and acepromazine (0.05 to 0.01 mg/kg IM) can be an effective premedication. The patient is oxygenated before handling.

Unless contraindicated, a combination of intravenous propofol and diazepam is used with minimal inhalant anesthesia concentrations. Occasionally a propofol constant-rate infusion is used. The use of perioperative antibiotics is debatable, and they are chosen on an individual case basis. Unless contraindicated, these patients typically receive one perioperative dose of dexamethasone SP (0.1 to 0.25 mg/kg intravenously [IV]).

The largest ET tube possible should be selected (at least 4 mm inner diameter) to facilitate passage of the stent delivery system while permitting oxygen delivery and ventilation during the procedure. An ET tube with a radiopaque line or markers should be used when possible to avoid inadvertent deployment of the stent within the tube. The use of sterile ET tubes is debatable; I do not routinely require them. Following intubation the patient is placed in lateral recumbency.

A wet hydrophilic guidewire (Weasel Wire, Infiniti Medical) and flushed marker catheter (Marker Catheter, Infiniti Medical) combination is advanced into the mouth. Under fluoroscopic guidance the guidewire is gently advanced down the esophagus, and the marker catheter is advanced over the wire. The soft guidewire is always advanced first to avoid damage to the esophagus by the relatively stiffer marker catheter. The marker catheter is placed within the esophagus such that the radiopaque marks extend along the location of the tracheal collapse. The guidewire is then withdrawn.

Under fluoroscopic guidance the ET is withdrawn until the distal-most aspect is just beyond the larynx. The cuff is gently reinflated, and positive-pressure ventilation of 20 cm H₂O is held while a radiograph is taken. Subsequent measurements are used to determine the tracheal stent diameter as described previously. The radiographic landmarks previously obtained identifying the extent of the collapse are compared with those of the esophageal marker catheter to determine the length of stent necessary.

STENT PLACEMENT

Once the appropriately sized stent is chosen, it is removed from its packaging using sterile technique. The stent is prepared, and saline flushed according to manufacturer recommendations. A right-angle bronchoscope adapter (Fig. 145-7) is attached to the ET tube to facilitate passage of

Fig. 145-7 Bronchoscope adapter used to maintain the anesthesia circuit while passing the stent delivery system through the endotracheal tube through the bronchoscope opening.

the stent delivery system while maintaining the anesthesia circuit system and patient oxygenation. Before passing the stent, the patient should be positioned such that the cervical and intrathoracic tracheas are in a straight line to facilitate placement of the relatively inflexible delivery system (see Fig. 145-6).

Because the stent is radiopaque, it is easily visualized under fluoroscopy, even when constrained within the delivery system. *All manipulations should be performed under direct fluoroscopic guidance.* The stent is directed to span the previously determined length of collapse. With one hand on the hub (or the cannula) and the other hand on the Y-piece (sheath), the sheath is gently withdrawn while *simultaneously* advancing the cannula (hub) in equal proportions. If done appropriately, as the stent is deployed, the distal end of the stent will remain in the same location throughout deployment. *Under no circumstances* should the cannula (hub) be advanced while the sheath remains stationary. This will force the stent caudally and traumatize the tracheal mucosa. These same circumstances apply to stent reconstraintment. If the operator is unhappy with the location of the partially deployed stent, reconstraintment should be performed via simultaneous withdrawal of the cannula and advancement of the sheath to avoid dragging the stent across the tracheal mucosa. The operator should practice these techniques outside of the patient before introducing the delivery system into the ET tube.

Following complete stent deployment, the delivery system is carefully removed. This should be performed under fluoroscopic guidance as well to ensure that the delivery system nose cone does not engage the distal end of the stent on removal. Radiographs are taken to document the final position of the stent (see Fig. 145-6). The patient is recovered immediately, typically in an intensive care unit setting and often within an oxygen cage. To facilitate smooth recovery from general anesthesia, the use of butorphanol (0.1 to 0.2 mg/kg IV) and/or acepromazine (0.005 to 0.01 mg/kg IV) can be useful.

POSTOPERATIVE CARE AND FOLLOW-UP

Patients routinely are discharged 1 or 2 days after stenting with a 3- to 4-week tapering dose of prednisone (initial dose of 1 to 2 mg/kg/day orally [PO]), continued anti-tussive therapy (hydrocodone 0.25 mg/kg PO q6–12h or higher doses if tolerated), and occasionally antibiotics if indicated. Patients with bronchial collapse or an observed “expiratory push” during exhalation may benefit from bronchodilator therapy as well.

Owners should be warned to anticipate an initial dry cough that should improve over the following 3 to 4 weeks. If the patient has documented bronchial collapse as well, the owners should expect continued coughing in the future. The majority of patients will require lifelong medication following tracheal stenting (see Chapter 144). The initial recheck examination is approximately 2 weeks after stenting or sooner if problems arise. Repeat examinations are then made according to the patient's clinical signs but should be performed regularly (every 3 to 6 months if possible).

Chronic Bronchitis in Dogs

LYNELLE R. JOHNSON, *Davis, California*

Chronic bronchitis is characterized by inflammation of the conducting airways and results in a chronic cough. The etiology of inflammation is unknown, although environmental pollutants, second-hand smoke, or inhaled irritants could be partly responsible for the induction of inflammatory airway disease in dogs. Chronic, low-grade aspiration injury might also play a role. In human medicine the role of bacterial infection in the generation or exacerbation of chronic bronchitis is widely debated, and in dogs no specific role has been established. Because chronic bronchitis is a disease of exclusion, treatment of the disease is based on all clinical information gathered from the individual animal.

Chronic airway inflammation is reflected by neutrophilic infiltration of the bronchial mucosa, which results in release of proteases, elastases, and oxidizing products. Mucosal injury is repaired by proliferation of the epithelium and hyperplasia of the surrounding tissue. Ongoing injury leads to a vicious cycle of airway injury and repair. These changes result in accumulation of mucus within the airway, which obstructs airflow and leads to clinical signs of cough and exercise intolerance. Airway collapse often accompanies chronic bronchitis, perhaps because of weakening of cartilage from inflammatory mediators or from effects on airway smooth muscle. Histologic examination of mucosal biopsy specimens from dogs with chronic bronchitis reveals hypertrophy and hyperplasia of mucous glands and goblet cells, smooth muscle hypertrophy, fibrosis of the lamina propria, and epithelial erosion with squamous metaplasia. The character of these lesions confirms the chronicity of disease. When a diagnosis of chronic bronchitis is made, it must be recognized that therapy is directed only at controlling clinical signs; once initiated, this disease is likely never cured.

CLINICAL FINDINGS

Chronic bronchitis is defined by the presence of a daily cough for at least 2 months of the year that lacks a specific cause. Usually the cough is described as a dry and hacking, but it can be moist or productive when copious amounts of respiratory secretions are produced. It may be overshadowed by a “goose honk” cough in small-breed dogs that have concurrent tracheal or airway collapse. Dogs are typically healthy and relatively active, although in the later stages of disease, exercise intolerance or heavy breathing may be reported. Severely affected animals may have intermittent cyanosis or collapse.

Chronic bronchitis occurs primarily in middle-aged to older dogs, and any breed (large or small) can be affected. On physical examination dogs are often overweight.

Some dogs are tachypneic, whereas dogs severely affected by bronchitis can have prolonged expiration or an expiratory push. Thoracic auscultation can be normal but often reveals coarse, diffuse crackles. Expiratory wheezes also may be noted and are considered the hallmark of chronic bronchitis. Tracheal sensitivity is usually present because of nonspecific airway inflammation. Airway collapse may be suspected on detection of a snapping sound over the thoracic cage as the intrathoracic airway collapses on expiration. In small-breed dogs a murmur of mitral insufficiency is a common coincident finding. When present, hepatomegaly is likely caused by obesity.

DIAGNOSIS

The diagnosis of chronic bronchitis is one of exclusion. The history of a long-term cough in a clinically well animal is highly suggestive of chronic bronchitis; however, airway infection (*Mycoplasma*, *Bordetella*, parasites), collapse, foreign body, or neoplasia can cause similar clinical signs. Therefore the diagnosis is based on the history, clinical findings, chest radiographs, and airway sampling for bacterial culture and cytologic examination.

Clinicopathologic abnormalities typically are absent in dogs with chronic bronchitis. Thoracic radiography is an important part of the diagnostic workup, both to confirm the likelihood of chronic bronchitis and to rule out other conditions. Classically a generalized increase in interstitial or peribronchial infiltrates is found in dogs with chronic bronchitis. End-on bronchi (doughnuts) and airways seen in longitudinal section (tram lines) represent airway walls thickened by inflammation. In the most advanced cases radiographic evidence of bronchiectasis may be identified. However, radiographs are relatively insensitive for chronic bronchitis, and in a case-controlled evaluation only increased thickness of airway walls and increased numbers of visible airway walls differed between normal dogs and dogs with bronchitis (Mantis, Lamb, and Boswood, 1998). In my opinion, normal chest radiographs are found relatively often in dogs with chronic bronchitis and do not rule out the diagnosis.

Collecting airway samples by tracheal wash or bronchoscopy is recommended to characterize the cellular infiltrate in the airway and to rule out infectious causes of cough. Bronchoscopy is particularly useful when typical radiographic findings of bronchitis are lacking. Dogs with chronic bronchitis have airway hyperemia, the airway mucosa has a cobblestone or irregular appearance, and many have increased mucus lining the airway. In animals with long-standing bronchitis fibrous nodules can be seen protruding into the bronchial lumen.

Cytologically chronic bronchitis is characterized by a preponderance of nondegenerate neutrophils. Some dogs have a predominance of eosinophils in airway washings or mixed inflammation. The importance of an eosinophilic infiltrate has not been investigated in dogs with chronic bronchitis. It may indicate systemic hypersensitivity (e.g., related to gastrointestinal parasites or ectoparasite infestation) or suggest an allergic basis for disease. Alternatively increased eosinophils in airway fluid may reflect the stage of disease. In humans airway eosinophilia is seen in patients with acute exacerbation of disease and indicates that non-infectious irritants, viruses, and *Mycoplasma* should be ruled out as causes of acute inflammation (Saetta et al., 1994). Increased mucus is present in many airway samples, and Curschmann's spirals (bronchial casts of airway mucus) are sometimes noted. Epithelial cells and squamous metaplasia may also be seen on cytologic examination.

Although suppurative inflammation is present on cytologic examination, bacterial infection is not a significant problem in the majority of dogs with chronic bronchitis. The trachea and large airway of dogs are not sterile; therefore various species of commensal bacteria and oral flora can be found in tracheal wash or bronchoalveolar lavage samples despite careful attention to technique. True bacterial infections of the lower respiratory tract are characterized by quantitative cultures of bronchoalveolar lavage fluid yielding more than 1.7×10^3 CFU/ml, lack of squamous cells on cytology, and a variably increased percentage of neutrophils (Peeters et al., 2000). Previously stable animals with bronchitis that have an acute exacerbation of disease may be experiencing true bacterial infection because dogs with chronic bronchitis might aspirate oral bacteria during episodes of coughing or panting. Aspirated bacteria become trapped in the mucus of the lower airway and may overwhelm host defenses because of the abnormal environment in the lower airway and cause infection. The airway is thus colonized and infected, and a septic suppurative inflammation would be seen on cytologic examination. Because *Mycoplasma* is part of the normal oral flora and can exacerbate lower airway injury, special culture techniques should be performed for these microorganisms in bronchitic animals.

Pulmonary function tests or advanced imaging can be performed to assess the severity of gas exchange or gas flow abnormalities. Arterial blood gas analysis generally shows only mild-to-moderate hypoxemia. Hypercarbia is not detected until late in the disease when respiratory failure ensues. Nuclear ventilation scans can be performed and may reveal patchy areas of deficient ventilation (Padrid et al., 1990). Flow volume loops are commonly performed in humans to assess maximal air flow. Tidal breathing flow volume loops have been performed in dogs with chronic bronchitis and have shown reductions in expiratory flow and loop shapes similar to those seen in humans with chronic bronchitis; however, these tests are not widely available.

THERAPY

Antiinflammatory Agents

Clinical signs of chronic bronchitis are caused by airway inflammation, and therapy with glucocorticoids is

successful in resolving clinical signs in the majority of dogs. It is essential that infectious diseases be ruled out before the initiation of antiinflammatory treatment. In addition, it would seem wise to control coexisting diseases such as severe dental disease or congestive heart failure before using glucocorticoids.

Dosing of glucocorticoids should be tailored to the individual, with the severity of clinical signs, chronicity of disease, and general systemic health considered in decisions regarding treatment. Short-acting steroids such as prednisone or prednisolone are generally safe and effective in dogs with uncomplicated bronchitis. In the early stages of disease dogs often require dosages of glucocorticoids ranging from 0.5 to 1 mg/kg every 12 hours for 5 to 7 days to induce remission of clinical signs. As clinical signs abate, the dosage should be decreased by half every 5 to 7 days; and, when possible, drugs should be administered on an alternate-day basis to allow normalization of the pituitary-adrenal axis. Long-term therapy (2 to 3 months) can be anticipated in most cases, although discontinuation of medication may be possible. If disease worsens in the early stages of treatment, a return to the higher dose of glucocorticoid that controlled clinical signs is generally required. Alternatively treatment with inhaled steroids, bronchodilators, or antitussive agents can be added (see following paragraphs). Long-acting glucocorticoids such as dexamethasone, triamcinolone, and methylprednisolone acetate do not have a therapeutic advantage over prednisone and are associated with more severe derangements of the pituitary-adrenal axis. I have not used cytotoxic drugs or antihistamines in the treatment of chronic bronchitis.

To avoid systemic effects of glucocorticoids, inhaled medications can be considered in animals that tolerate administration via a face mask. Various types of steroids are available for inhalation in metered-dose inhaler canisters. I generally start with fluticasone propionate (Flovent, Glaxo Smith-Kline) using 110 mcg/puff- or 220 mcg/puff-strength administered at 1 puff BID to QID. To avoid the need for a voluntary respiratory maneuver to inhale the medication, the drug is dispensed using a spacing chamber and face mask. Spacing chambers are available through a variety of respiratory supply corporations or pharmacies; a tight-fitting face mask is critical for successful therapy. It is important that the dog have the nose and lips enclosed by the mask during actuation of the drug and that it breathes normally for 8 to 10 seconds (i.e., does not pant). Brachycephalic dogs are easily fit with face masks obtained from a local pharmacy or respiratory supply company because the shape of the face is more similar to that of humans. For dolichocephalic breeds, anesthetic or cone-shaped face masks are required, and an up-sizing adaptor may be required to fit properly on the spacer.

Bronchodilators

It is unlikely that bronchoconstriction plays a role in canine chronic bronchitis. Baseline pulmonary resistance increased in an experimental model of lung inflammation induced by *Bordetella bronchiseptica*; however, airway responsiveness as assessed by histamine challenge was unchanged (Cormier et al., 1993). The baseline increase in resistance

was probably related to the presence of inflammatory products and mucosal edema rather than airway hyperactivity. However, bronchodilators often are clinically helpful in reducing signs in dogs with bronchitis or in allowing a reduction in the dosage of glucocorticoid required to control signs. Both methylxanthine derivatives and β -agonists seem to act synergistically with glucocorticoids in the control of inflammatory lung disease. Bronchodilators may provide other beneficial effects by improving pulmonary perfusion, enhancing cardiac performance, reducing respiratory effort, and stimulating mucociliary clearance. In dogs that fail to respond adequately to glucocorticoids, a 2-week trial on a supplemental bronchodilator is a reasonable therapeutic option.

The two main classes of bronchodilators used in veterinary medicine are methylxanthine derivatives and β_2 -agonists. Methylxanthine drugs were originally thought to act through phosphodiesterase inhibition, which causes smooth-muscle relaxation through accumulation of cyclic adenosine monophosphate. Current research suggests that the clinical effects of methylxanthines result from adenosine antagonism. Extended-release theophylline (Inwood Laboratories, 10mg/kg orally [PO] q12h) has been shown to achieve plasma levels in dogs that approximate the human therapeutic range of 10 to 20mcg/ml (Bach et al., 2004).

Adverse effects of methylxanthines are probably also related to adenosine antagonism and include gastrointestinal upset, tachycardia, and hyperexcitability. It is essential to individualize drug therapy because there is a wide variation in the dose that causes side effects. Theophylline metabolism is influenced by many factors, including fiber in the diet, smoke in the environment, congestive heart failure, and the use of other drugs. I recommend starting therapy with half the recommended dosage (5mg/kg q12h) for the first week to reduce adverse side effects. If clinical signs improve and the dog tolerates the drug, the dosage may be increased as needed.

β_2 -Agonists such as terbutaline and albuterol have also been used successfully in dogs with chronic bronchitis. Terbutaline is available through a wide number of pharmaceutical companies. Small dogs receive 0.625 to 1.25 mg orally every 12 hours, medium-sized dogs are given 1.25 to 2.5 mg orally every 12 hours, and larger dogs receive 2.5 to 5 mg orally every 12 hours. Albuterol at 50mcg/kg orally every 8 hours was efficacious in reducing cough in almost half the dogs evaluated in a review of canine chronic bronchitis (Padrid et al., 1990). Interestingly, the bronchodilator also resulted in a reduction in the severity of the pulmonary infiltrate. As with methylxanthines, β -agonists may result in excitability or tremors during initial therapy, but animals usually become accustomed to the drug. β_2 -Agonists are widely available for inhaled therapy and are inexpensive.

Antibiotics

When infection has been documented through appropriate culturing techniques and cytologic findings confirm infection, antibiotic treatment is warranted. Antibiotic choice should be based on culture and sensitivity results whenever possible and should have a broad spectrum of activity against bacteria commonly found in the lung such as *Pasteurella* spp., *Staphylococcus* spp., *Streptococcus* spp., and various

gram-negative species. The antibiotic chosen should be lipophilic to facilitate penetration of the airway and should be relatively free of side effects. When possible, I prefer doxycycline (3 to 5 mg/kg PO q12h) because this drug has all of the desired attributes and is relatively devoid of side effects. Owners should be instructed to supply water after administering the drug to propel the pill fully into the stomach, thus avoiding the possibility of an esophageal stricture caused by delay in esophageal transit. Enrofloxacin (Baytril [Bayer], 2.5 to 5 mg/kg PO q24h) is generally reserved for severe infection. If needed, it is important to note that enrofloxacin inhibits metabolism of theophylline and the concurrent use of the two drugs results in toxic plasma levels of theophylline (Intorre et al., 1995). At least a 30% reduction in theophylline dosage is recommended when enrofloxacin is required to treat coincident infection. Length of antibiotic treatment depends on whether pneumonia is present or whether bronchial colonization and infection are suspected. True pneumonia generally requires 3 to 6 weeks of antibiotic therapy, whereas 5 to 10 days of treatment usually resolve signs related to bronchial colonization. If *Bordetella* is isolated from an airway wash, aerosolization with gentamicin (Gentocin, Schering Plough) would be recommended rather than oral antibiotics because of improved efficacy in reducing bacterial numbers in the airway (Bemis and Appel, 1977), although some dogs do seem to respond to long-term doxycycline. An ultrasonic nebulizer and face mask are used to administer 3 to 5 mg/kg of gentamicin once daily for 5 days.

Infection plays a predominant role in patients with concurrent bronchiectasis, and in these patients long-term antibiotic therapy is indicated. Bronchiectasis is defined as a dilation of the lower airways; suppuration is usually present. It may occur as a sequela to uncontrolled airway inflammation or infection. Mucus trapping and obstruction of the airway are severe, and recurrent pneumonia is commonly encountered. Chronic antibiotic therapy is often required in these patients, and broad-spectrum antibiotics or combinations of antibiotics should be chosen because infection may involve various gram-negative bacteria (especially *Pseudomonas*) and anaerobes. Chloramphenicol, trimethoprim-sulfa (15 mg/kg PO q12h), or clindamycin (Antirobe [Pharmacia & Upjohn], 11 mg/kg PO q12h) combined with enrofloxacin can be helpful in resolving long-standing pulmonary infection.

Antitussive Agents

The cough reflex is of major importance to the dog with bronchitis because it serves the essential function of clearing viscid secretions from the airway. Suppression of this reflex before resolution of inflammation can be deleterious because mucus can become trapped in small airways. Prolonged contact between inflammatory mediators in the mucus and epithelial cells perpetuates airway inflammation. When clinical signs suggest that inflammation is resolving yet the cough persists or in animals that have concurrent airway collapse with chronic bronchitis, cough suppression is desirable because chronic coughing can lead to repeated airway injury and syncopal events. Over-the-counter dextromethorphan-containing compounds seem to be useful in some animals. When more potent suppression of a dry cough is required, narcotic agents should be prescribed.

I prefer hydrocodone (Tussigon [Daniels Pharmaceuticals], 0.22 mg/kg PO q6–12h) or butorphanol (Torbutrol [Fort Dodge], 0.5 mg/kg PO q6–12h). These agents must be given at an interval that suppresses coughing without inducing excessive sedation or gastrointestinal effects. Long-term therapy may be required in some patients, particularly when tracheal collapse is also present.

ADDITIONAL THERAPY

Obesity worsens clinical signs in dogs with chronic bronchitis by decreasing thoracic wall compliance, increasing the work of breathing, and increasing abdominal pressure on the diaphragm. Improvements in exercise tolerance and arterial oxygenation can be seen with weight loss alone. Owners should be given reasonable goals for the dog's optimal weight and the time in which weight loss can be achieved. A 2% to 3% weight loss per week is desirable. This can be achieved through the use of a high-fiber, low-fat diet and by providing gradually increasing amounts of exercise. Close monitoring of owner compliance and accomplishments in the weight-loss program seems to enhance the overall success.

Animals with concurrent tracheal collapse or marked tracheal sensitivity benefit from having a harness instead of a collar. When stresses in the environment such as cigarette smoke, pollutants, heat, or humidity are encountered, the animal should be removed to a cool, clean area.

Some dogs benefit from intermittent airway humidification via steam inhalation or nebulization to improve clearance of airway secretions. An ultrasonic nebulizer is preferred for respiratory therapy because it produces sufficiently small particles of saline to penetrate deep into the airways. Coupage of the chest or gentle exercise after nebulization facilitates clearance of secretions.

PROGNOSIS

Owners should be aware that bronchitis is a chronic disease that can be controlled but never cured. The majority of animals have residual cough and exhibit clinical signs periodically throughout life. The presence of fibrosis and chronic inflammation on biopsy specimens confirms the irreversibility of airway disease. The goals of disease management are to control inflammation, thus limiting clinical signs; to diagnose and treat infection when it occurs; and to prevent the development of debilitating sequelae such as bronchiectasis and cor pulmonale.

Bordetella bronchiseptica: Beyond Kennel Cough

RICHARD B. FORD, *Raleigh, North Carolina*

With the capacity to exist in the respiratory tract as a commensal organism and a pathogen, *Bordetella bronchiseptica* poses a unique and nearly ubiquitous threat to both dogs and cats of all ages. Most frequently implicated for its role in infectious tracheobronchitis (ITB) in dogs (also called *kennel cough*), clinical illness associated with colonization of *B. bronchiseptica* is ultimately defined by the ability of the bacterium to express various virulence factors, or determinants. Although the respiratory epithelium of the nasal cavity and trachea are principle targets of infection and a particularly common source of infectious cough and pneumonia, systemic infection associated with bacteremia and sepsis is reported.

THE BORDETELLAE

There are nine known *Bordetella* spp., four of which have been associated with respiratory infections in humans and other mammals: *Bordetella pertussis*, *Bordetella parapertussis*, *Bordetella holmesii*, and *B. bronchiseptica*. Associated with pertussis, or “whooping cough,” *B. pertussis* and *B. parapertussis* are host-restricted human pathogens, most commonly associated with respiratory infection in children. On the other hand, *B. holmesii* has only been associated with respiratory illness in a limited number of humans since 1995. *B. bronchiseptica*, first isolated in the early 1900s, is somewhat unique in that it is able to infect the respiratory tract of several species of mammals, including humans (Mattoo and Cherry, 2005).

B. bronchiseptica is a gram-negative aerobic coccobacillus particularly well adapted to colonize the ciliated respiratory epithelium of dogs and cats. Today this organism is regarded as a principle bacterium associated with canine ITB (Ford, 2006). Dogs infected with canine parainfluenza virus (CPIV) or canine adenovirus-2 (CAV-2) may experience more severe respiratory disease when coinfecting with *B. bronchiseptica*. *B. bronchiseptica* infection in the absence of either CPIV or CAV-2 (i.e., canine bordetellosis) is known to occur and can be associated with acute, fatal pneumonia, particularly in young dogs. Several commercial vaccines are available today and have been shown to induce high titers. However, *B. bronchiseptica* has been isolated from the nasal cavity of vaccinated animals, suggesting that vaccination does not necessarily prevent infection.

Virulence Factors and Pathogenesis

The complexity of *B. bronchiseptica* infection is characterized by its ability to become colonized persistently in

the upper and lower respiratory tract yet cause no clinical signs or gross pathology. Histologic examination following experimental inoculation only rarely demonstrates inflammatory changes. When clinical signs associated with *B. bronchiseptica* do develop in dogs, the disease is characterized as tracheobronchitis. Congestion of tracheal and bronchial mucosa occurs with mucoid-to-mucopurulent exudates in airways. Lung parenchyma may also become infected since focal exudative pneumonia and petechiae are also reported. The most severe consequences of infection generally are seen in dogs and cats coinfecting with other pathogens such as CPIV or feline calicivirus.

B. bronchiseptica exists both as a commensal organism in the respiratory tract of healthy dogs and cats and as a potentially life-threatening pathogen. The outcome of infection is highly variable and difficult to predict in the clinical setting. The complexity of this bacteria-host interaction is attributed to the fact that *B. bronchiseptica* possesses a virulence control system nearly identical to that found in *B. pertussis* and *B. parapertussis*, encoded by the *BvgAS* locus. *Bordetella* virulence genes A and S (*BvgA* and *BvgS*, respectively) are signaling proteins responsible for the expression of several virulence determinants (Table 147-1) and ultimately the pathologic consequences of infection.

The *BvgAS* locus controls at least three distinct phenotypic phases of *B. bronchiseptica*: *Bvg*⁺, *Bvg*ⁱ, and *Bvg*⁻, which are believed to be involved with colonization, transmission, and survival (persistence), respectively. Interestingly, expression of a particular phase appears to be under the influence of various environmental conditions (such as coinfection or stress). The relevant signals that influence and regulate the *BvgAS* locus have yet to be determined.

Clinical Disease

In contrast to *B. pertussis* and *B. parapertussis*, which only infect humans, *B. bronchiseptica* is uniquely able to infect several species of mammals, including humans. Transmission of *B. bronchiseptica* occurs primarily through aerosolization of respiratory secretions. Bacteria can also be transmitted directly by contaminated dishware, human hands, and other fomites. Because *B. bronchiseptica* possesses several intrinsic mechanisms for evading host defenses, it is recognized for its role as a significant complicating factor in dogs with multiple-agent respiratory infections. The clinical consequences of infection range from subclinical

Table 147-1

Principle Virulence Determinants for *Bordetella bronchiseptica* and Summary of Actions

Virulence Determinant	Action
Filamentous hemagglutinin	Surface-associated and secreted protein; required for tracheal colonization; highly immunogenic
Fimbriae	Filamentous cell surface structure required for persistent tracheal colonization
Pertactin	Surface protein; enhances protective immunity
Vag8	Outer membrane protein
Adenylate cyclase	Calmodulin-activated toxin with dual adenylate cyclase/hemolysis activity; acts as an antiinflammatory and antiphagocytic factor during infection
Type III secretion	Allows <i>Bordetella</i> to translocate effector proteins into host cells; required for persistent tracheal colonization; inhibits host immune response; causes cell death
Dermonecrotic toxin	Heat-labile toxin; induces necrosis in vitro
Tracheal cytotoxin	Causes mitochondrial bloating, disruption of tight junctions, and damage to ciliated cells

From Mattoo and Cherry, *Clin Microbiol Rev* 18:326, 2005.

disease with shedding to suppurative pneumonia and death, especially in puppies.

B. bronchiseptica is frequently, although not exclusively, associated with canine ITB (i.e., kennel cough). The bacteria are commonly recovered from dogs with signs of upper and lower respiratory infection subsequent to having been housed in cluster environments such as boarding kennels, veterinary hospitals, and animal shelters. In addition, *B. bronchiseptica* recently has been reported as the most common cause of community-acquired infectious pneumonia in dogs less than 1 year of age (Radhakrishnan et al., 2007). Such findings support the fact that *B. bronchiseptica* is widely distributed throughout the canine population and poses a significant threat to susceptible dogs and to a lesser extent cats.

In practice the clinical signs vary considerably, depending on the extent of coinfection or the presence of another underlying respiratory disease. Typically dogs infected with *B. bronchiseptica* manifest clinical signs that range from purulent nasal discharge (without cough) to paroxysmal coughing episodes. In cats *B. bronchiseptica* infection is most commonly associated with lower respiratory signs characterized by cough, particularly in kittens. Clinical signs caused by *B. bronchiseptica* generally are described as self-limiting and in otherwise healthy animals are expected to last no more than about 2 weeks. Although clinical signs of *B. bronchiseptica* infection are reported to persist for only 1 to 2 weeks, bacteria can be shed from the respiratory tract for 2 to 3 months following recovery. Resistance to reinfection may last up

to 12 months. Dogs with signs persisting beyond 2 weeks should be evaluated for another underlying disease as the principle cause of cough.

Severe bronchopneumonia is described in dogs with no prior natural or vaccine exposure to the various agents that cause ITB or complicating bacterial infection. Affected dogs are likely to have a history of recent stays in a pet shop, boarding facility, kennel, or shelter. ITB may be associated with or without rhinitis and accompanying mucoid-to-mucopurulent nasal and ocular discharge. Complications associated with bronchopneumonia may become life threatening, particularly in puppies. On physical examination affected dogs are usually febrile and may be lethargic, anorexic, and dyspneic. Affected dogs are difficult to distinguish from those with canine distemper virus (CDV) infections or other pneumonias. Outbreaks of infectious pneumonia caused by *B. bronchiseptica* may affect more than 50% of dogs in a densely populated environment.

Several published reviews on bacterial endocarditis and sepsis in dogs and cats implicate *B. bronchiseptica* as common causative bacteria. Although the route of entry has not been characterized, *bordetella* is known for its ability to infect the cilia of respiratory epithelial cells. Ciliostasis subsequent to initial infection is followed by mucus production, damage to epithelium, and induction of an inflammatory response with the respiratory tract (Anderton, Maskell, and Preston, 2004). Injury to epithelial cells may represent a portal of entry into blood that in some patients culminates in bacteremia and sepsis with or without clinical evidence of respiratory tract infection.

Determining the actual prevalence of *B. bronchiseptica*-induced respiratory disease in dogs and cats is complicated by the facts that: (1) infectious respiratory disease is typically associated with other bacterial pathogens (e.g., *Mycoplasma* spp.) and viruses (e.g., parainfluenza virus, CDV, and calicivirus; and (2) *B. bronchiseptica* can be isolated from the respiratory tract of healthy dogs and cats (Moise et al., 1989).

Diagnosis

In the clinical setting diagnostic confirmation of *B. bronchiseptica* infection by culture is uncommon. Instead a clinical diagnosis of ITB is made on the basis of history and signs. Diagnostic confirmation entails collecting nasal swabs or fluid collected aseptically from a tracheal aspiration or bronchoscopic washing. These studies most commonly are done in patients with radiographic signs of bronchopneumonia or when coughing associated with kennel cough persists despite empiric antibiotic therapy. Airway samples are inoculated onto commercially available Bordet-Gengou agar supplemented with 0.004% cephalixin or 20 mcg of streptomycin and incubated for 48 hours at 37°C. Identity can be confirmed by use of a Gram stain.

Treatment

Therapy for any dog or cat with known or suspected respiratory infection caused by *B. bronchiseptica* varies with the severity of disease and the presence of an underlying disorder. Prompt antimicrobial intervention is important and may be lifesaving. Doxycycline is the preferred

antimicrobial used in the treatment of infectious respiratory disease of dogs and cats. Tablets, capsules, or a liquid suspension may be administered at 5 mg/kg orally twice daily for 7 to 10 days. Alternatively doxycycline may be administered once daily at a dose of 10 mg/kg. The liquid suspension is preferred when treating cats and puppies. Although oral doxycycline can discolor the enamel of developing teeth in young animals, limiting the treatment to fewer than 10 days minimizes the risk. Shorter treatment durations (e.g., 5 to 7 days) have been effective in treating young puppies with severe bronchopneumonia caused by *B. bronchiseptica*. Azithromycin, amoxicillin-clavulanate, and cephalexin are alternative antimicrobials that could be used in lieu of doxycycline.

Although corticosteroids are recommended in the management of cough associated with viral tracheobronchitis in dogs, these drugs are contraindicated in any patient known to have pneumonia caused by *B. bronchiseptica*. Therefore empiric treatment should be limited to antibacterial therapy until a response to treatment can be evaluated.

Cough suppressants, including butorphanol and various forms of codeine, are often used in the treatment of kennel cough in dogs. When the infection is related only to a viral injury, judicious reduction of cough may be helpful to the patient (and client). However, in cases of bacterial infection caused by *B. bronchiseptica*, the response to antibiotics should be sufficient to reduce clinical signs of coughing, and antitussive therapy is not recommended. Furthermore, if bronchopneumonia is developing, suppression of cough can be dangerous by preventing clearance of bacteria, infected mucus, and other debris. Accordingly a chest radiograph should be considered before initiating any antitussive therapy, and the initial response to antibiotic therapy should be considered as a guide before attempting to suppress a kennel cough. This is especially true if there is fever or any constitutional signs of infection such as lethargy or anorexia.

Administration of fluids, either orally or parenterally, is indicated in any dog or cat with bacterial infection of the lower respiratory tract. Fluid therapy is particularly important in puppies and kittens with bacterial pneumonia. Within 24 hours significant insensible fluid loss through the respiratory tract can lead to increased viscosity of secretions, decreased clearance of lower airways, and greater risk of death.

Indications for nebulization, oxygen therapy, and coupage in patients with bacterial pneumonia are presented in detail in Chapter 149.

Vaccination

B. bronchiseptica vaccines are licensed in the United States for administration to both cats and dogs. The 2006 Report of the American Animal Hospital Canine Vaccine Task Force has classified all *B. bronchiseptica* vaccines as noncore. A parenteral, cellular antigen extract vaccine and an intranasal avirulent live vaccine are currently available for use in dogs. All *B. bronchiseptica* vaccines approved for intranasal administration in dogs contain modified-live parainfluenza vaccine. Some intranasal vaccines approved for use in

dogs also contain modified-live CAV-2 vaccine.* The only vaccine licensed for use in cats is an avirulent-live bacterial vaccine approved for intranasal administration only.

Canine Vaccination

The availability of both parenteral and intranasal *B. bronchiseptica* vaccine for dogs has led to questions concerning efficacy, onset of action, frequency of administration, and safety. Today most authors agree that both vaccine types are effective in reducing the severity of clinical illness (Edinboro et al., 2004; Gopinathan et al., 2007). No one vaccine type is known to be significantly better at reducing clinical illness than the other. However, *neither* parenteral nor intranasal vaccine appears to prevent infection subsequent to natural exposure.

Compared to parenteral *B. bronchiseptica* vaccine, intranasal vaccines provide a significantly faster onset of immunity at the time of initial vaccination. A single dose of intranasal vaccine has been shown to protect dogs against clinical illness as early as 72 hours, with most dogs responding by 4 to 14 days (Gore et al., 2005). Intranasal vaccines can be administered to puppies as young as 3 to 4 weeks of age.

On the other hand, initial vaccination with the parenteral vaccine *requires* that two doses be administered 3 to 4 weeks apart. Immunity cannot be expected for at least 1 to 2 weeks following administration of the second dose. The first of two doses should not be administered before 6 weeks of age. If the vaccination interval between the first and second parenteral doses exceeds 6 weeks, the entire two-dose series should be repeated. Two doses of parenteral vaccine result in higher antibody titers compared to titers derived from a single intranasal booster vaccination. However, antibody titers are less valid in assessing vaccine-induced immunity to *B. bronchiseptica* than are controlled challenge studies.

Challenge studies designed to assess the duration of immunity following vaccination are limited. However, there is reasonable evidence to support a sustained immune response lasting from between 10 and 14 months following intranasal vaccination. The duration of immunity following administration of the parenteral vaccine has not been published.

Current recommendations suggest that a single dose of either an intranasal or parenteral vaccine administered annually is sufficient to boost an individual patient's immunity. It is my opinion that annual booster with either vaccine type is sufficient for dogs having minimal risk of exposure. However, in the face of sustained exposure (e.g., regular boarding, dog day care), it is reasonable to recommend vaccination every 6 months as long as the risk of exposure exists. Although *B. bronchiseptica* is not the only pathogen associated with canine infectious respiratory disease, vaccination against *B. bronchiseptica* is justified because of its ability to seriously compromise the patient.

*The 2006 American Animal Hospital Association Canine Vaccine Guidelines recommend against the use of intranasal CAV-2 vaccine on the grounds that parenteral CAV-2 vaccine is considered to confer a superior immune response in preventing CAV-1 (canine infectious hepatitis virus) infection.

A recent study (Davis et al., 2007) has shown that intranasal vaccination prevents postchallenge shedding of bacteria, whereas the parenteral vaccine did not. Such studies support recommendations that either vaccine may be appropriate for use in households with one to two dogs. However, the intranasal vaccination is indicated to minimize transmission of *B. bronchiseptica* among dogs housed in a cluster environment (e.g., shelters, rescue groups).

Feline Vaccination

Currently only one feline vaccine is available for the prevention of *B. bronchiseptica* in cats. The vaccine consists of avirulent live bacteria and is administered to kittens as young as 4 to 6 weeks of age. Much less is known about the significance of *B. bronchiseptica* in the pathogenesis of feline infectious respiratory disease. As in dogs, the presence of *B. bronchiseptica* can cause pneumonia and seriously compromise respiratory function, particularly in kittens. It is possible that kittens coinfecting with acute feline calicivirus or herpesvirus-1 may experience severe, even fatal, clinical illness in the presence of bacteria. Vaccination should be limited to kittens and young cats with a reasonable risk of exposure to other cats or dogs. The manufacturer recommends that annual boosters be administered to cats considered to be at risk of exposure. However, annual vaccination of healthy adult cats having little or no risk of exposure to cats or potentially infected dogs generally is not recommended.

Vaccine Complications

Clinical signs of respiratory disease, including purulent nasal discharge and cough, have been reported in both dogs and cats within a few days following intranasal vaccination. In most instances these signs resolve without treatment. However, some patients may become clinically ill and actually require short-term treatment with an antimicrobial. Postvaccinal nasal discharge and/or cough seem to occur more often in young animals than adults.

Inadvertent subcutaneous administration of the avirulent, live intranasal *B. bronchiseptica* vaccine is reported occasionally. Injection site abscess seems to be the most common physical manifestation. However, replication of the attenuated gram-negative bacteria in the subcutaneous space has been associated with death following liver failure. Endotoxemia rather than sepsis is speculated to be the cause. Anecdotal reports from practicing veterinarians suggest that some dogs do not manifest any adverse signs or illness. Treatment of a dog or cat that inadvertently receives the intranasal vaccine by the subcutaneous route includes administration of oral doxycycline, 5 mg/kg every 12 hours for 5 to 7 days.

It has been suggested that intranasal vaccine might have therapeutic benefit in dogs with active clinical signs consistent with ITB. However, in my experience in

attempting to treat dogs involved in a shelter outbreak of infectious respiratory infection, intranasal vaccine neither lessened the severity of clinical signs nor did it shorten the course of infection. Intranasal vaccine should not be used in the attempt to treat preexisting respiratory infection.

Human Infection With *Bordetella bronchiseptica*

Of importance to veterinarians is the fact that *B. bronchiseptica* can be transmitted from animals (e.g., dogs, cats, rabbits) to other animal species and humans. Although generally considered to be rare and limited to individuals with immune compromise, unverified infections in humans have been reported (Woolfrey and Moody, 1991). The role of *B. bronchiseptica* as a zoonotic pathogen, particularly for those working directly with animals in high-density environments (e.g., shelters, rescue organizations) warrants additional study.

Chronic Bronchitis and Asthma in Cats

PHILIP PADRID, *Chicago, Illinois*

Chronic bronchial disease in cats occurs most commonly in two forms: chronic bronchitis and asthma. *Chronic bronchitis* is defined as an inflammatory disorder of the lower airways that causes a daily cough, for which other causes of cough (including heartworm disease, pneumonia, lungworms, and neoplasia) have been excluded. *Asthma* is more loosely defined as a disorder of the lower airways that causes airflow limitation, which may resolve spontaneously or in response to medical treatment. *Airflow limitation* is generally the result of some combination of airway inflammation, accumulated airway mucus, and airway smooth muscle contraction. The symptoms of asthma can be dramatic, including acute wheeze and respiratory distress. However, sometimes the only symptom of asthma-induced airflow limitation is a daily cough; in humans this is referred to as *cough-variant asthma*.

Definitive diagnosis of asthma is usually based on specific pulmonary function studies that require patient cooperation. Because both disorders, bronchitis and asthma, can cause a daily cough as the only clinical sign, there are many times when it is not possible to distinguish bronchitis from asthma in the feline patient. Nevertheless the diagnosis, prognosis, and treatment options for both diseases overlap with great frequency. The purposes of this article are to (1) review our current understanding of the pathophysiology of bronchial disease and asthma in cats, (2) review common clinical signs and diagnostic tests, (3) suggest rational and novel approaches for treating cats with these debilitating and frequently confusing airway disorders, and (4) discuss reasonable expectations for long-term care.

DIAGNOSIS

Reversible bronchoconstriction is one of the defining features of asthma and can be used to distinguish asthma from chronic bronchitis when the two diagnoses are not clearly separable by clinical means. However, demonstration of reversible bronchoconstriction via pulmonary function studies generally requires patient cooperation, and the equipment and expertise needed to perform these kinds of tests are not available in general veterinary practice. One maneuver can point the practitioner toward a diagnosis of asthma. If a patient is wheezing during the physical examination, I administer terbutaline by inhalation or parenterally (0.01mg/kg intramuscularly [IM]) and reevaluate the patient in 5 to 10 minutes. Resolution of the wheezing implies bronchoconstriction that was

reversible and the result of the bronchodilating effects of the medication.

With the exception of this one maneuver, there are no specific tests practical for a general practice that can be used for definitive diagnosis of asthma or bronchitis in cats. Therefore I generally rely on clinical criteria, including:

- A history that includes one or more of these clinical signs: acute wheeze; tachypnea; or respiratory distress, including labored, open-mouth breathing. These signs are usually relieved quickly with some combination of oxygen, bronchodilators, and corticosteroids. The diagnosis of chronic bronchitis requires the presence of a daily cough. In some cases of asthma the only clinical problem may be daily or intermittent chronic cough.
- Radiographic evidence of bronchial wall thickening, usually described as *doughnuts* and *tramlines*. Air trapping may be evidenced by hyperinflated airways. This is seen most prominently on the lateral view and can be appreciated by recognizing the position of the diaphragmatic crus at approximately the level of L1-L2. Radiographs may also demonstrate atelectasis, most commonly of the right middle lung lobe. It is usually easier to see this pattern on a dorsoventral or ventrodorsal exposure because the right middle lung lobe silhouettes with the cardiac silhouette on the lateral view. Atelectasis most commonly occurs in the right middle lung lobe because of mucus accumulation within the bronchus; this airway is most commonly involved because it is the only airway that has a dorsoventral orientation within the bronchial tree and therefore is subject to the effects of gravity.
- Clinicopathologic evidence of airway inflammation, including the finding of large numbers of eosinophils recovered from tracheobronchial secretions in asthmatic airways and nonseptic neutrophils in bronchitic airways.

Response to Therapy As a Diagnostic Measure

Cats with asthma may stop coughing or wheezing within 10 minutes after administration of a bronchodilator. The great majority of cats with bronchitis or asthma respond to high-dose corticosteroid therapy within 5 to 7 days; a patient with a diagnosis of bronchitis or asthma that responds poorly should be reevaluated, and the diagnosis revisited.

These clinical findings, including reversible bronchoconstriction and airway inflammation, are strikingly similar to the clinical findings in human asthma. Histologic similarities include hyperplasia and hypertrophy of the mucus-secreting apparatus and airway smooth muscle hyperplasia. Epithelial erosion also is frequently found in association with an eosinophilic infiltrate. Airway hyperactivity, a defining feature of human asthma, has also been documented in cats with experimentally induced and naturally occurring asthma.

PATHOPHYSIOLOGY

The potential causes of bronchitis and asthma are numerous; however, the airways are capable of responding to noxious stimuli in a limited number of ways. Airway epithelium may hypertrophy, undergo metaplastic change, erode, or ulcerate. Airway goblet cells and submucosal glands may hypertrophy and produce excessive amounts of viscid mucus. Bronchial mucosa and submucosa are usually infiltrated with variable numbers and types of inflammatory cells and may become edematous. Bronchial smooth muscle may remain unaffected, become hypertrophied, or spasm. In almost all cases the unifying and underlying problem is chronic inflammation, but the exact cause remains unproven.

The resulting clinical signs of cough, wheeze, and lethargy are caused by limitation of airflow from excessive mucus secretions, airway edema, and airway narrowing from cellular infiltrates. In addition, cats with asthma may suffer acute airway narrowing from airway smooth muscle constriction. A 50% reduction in the luminal size of an airway results in a 16-fold reduction in the volume of air that flows across that airway. Clearly even small changes in airway diameter can result in dramatic changes in airflow. The clinical implications of this finding are twofold. First, relatively small amounts of mucus, edema, or bronchoconstriction can partially occlude airways and cause a dramatic fall in airflow. Conversely, therapy that results in relatively small increases in airway size may cause a dramatic improvement in clinical signs.

Cough may also result from stimulation of mechanoreceptors located in inflamed and contracted airway smooth muscle. Inappropriate airway smooth muscle contraction, in turn, seems fundamentally linked to inflammation. Although many inflammatory cell types are found within asthmatic airways of humans and cats, eosinophils appear to be primary effector cells in the development of asthmatic airway pathophysiology in both species. Highly charged cationic proteins within eosinophil granules are released into airways and cause epithelial disruption and sloughing. In addition, these granular proteins can make airway smooth muscle more "twitchy" and prone to contraction after exposure to low levels of stimulation (airway hyperactivity).

Eosinophil-T Lymphocyte Interactions

The pathogenesis of asthmatic airway hyperactivity is clearly multifactorial. Numerous investigations suggest that the interaction between T lymphocytes and eosinophils within airways may play an important role in the

generation of airway inflammation and airway hyperactivity in human asthma (Beasley et al., 1989; Bradley et al., 1991; NHLBI statement, 2006). Increased numbers of eosinophils and activated T lymphocytes are found in bronchoalveolar lavage (BAL) specimens and bronchial mucosa of patients with asthma. The presence of these cells is correlated with disease severity. Activated T cells are recruited into the airways of asthmatic individuals when they are exposed to aeroallergens. These CD4-positive lymphocytes (among other cells) secrete interleukin-5 (IL-5) to promote eosinophilopoiesis, survival, activation, and recruitment into airways. A Th2-driven cytokine profile has been demonstrated in antigen-induced asthma models in the feline species (Reinero et al., 2004).

Studies in Naturally Occurring Disease

Although coughing and wheezing cats have been identified by owners and veterinarians for almost a century, only in the last 15 years have veterinarians begun to study the disorder in earnest. Dye and associates (1996) identified pulmonary function abnormalities in cats with signs of chronic lower airway inflammation. Some of these cats had increased pulmonary resistance that resolved after treatment with terbutaline, a β_2 -agonist, indicating the presence of reversible bronchoconstriction in these patients. In addition, some of these cats experience dramatic bronchoconstriction after exposure to low levels of methacholine, a drug with minimal effects on pulmonary function when used in equivalent doses in nonasthmatic cats. This was the first demonstration of *spontaneous*, naturally occurring airway hyperactivity and reversible bronchoconstriction in a nonhuman species. In addition, histologic changes in airways from asthmatic cats include epithelial erosion, goblet cell and submucosal gland hyperplasia and hypertrophy, and an increased mass of smooth muscle, which are features of human asthmatic airways. Additional reviews have demonstrated the variation in clinical findings, radiographic patterns, and responses to therapy in cats with bronchitis and asthma (Adamama, 2004; Foster, 2004). This likely is a result of differences in staging these disorders and the fact that other disorders, including pulmonary fibrosis and occult heartworm infection, can mimic the symptoms of bronchial disease in cats (Cohn, 2004; Dillon, 2007).

Experimentally Induced Feline Asthma

Studies of cats with naturally occurring asthma are critical to the understanding and formulation of rational treatment strategies. However, diagnostic studies required for definitive diagnosis use specialized equipment and often require an anesthetized patient. This has limited evaluation of cats with spontaneous disease, and our understanding of the pathogenesis and natural course of asthma in cats has been hampered as a result. Recent technologic advances have allowed us to study pulmonary function in awake, unsedated cats and should yield new insights into the mechanisms of disease.

Experimental models of feline asthma have been developed to better understand the immunologic mechanisms

operative in the pathogenesis and perturbation of asthma and as a means to objectively determine responses to therapy. The first model of feline asthma involved antigen sensitization and chronic aerosol challenge with *Ascaris suum* as an antigen. These cats developed persistent airway eosinophilia and hyperresponsiveness to nebulized acetylcholine along with typical morphologic changes observed in spontaneous bronchial disease of cats. These antigen-sensitized cats have elevated serum levels of soluble receptor for IL-2 found within 24 hours of antigen challenge and a decrease in the CD4:CD8 peripheral blood T cell ratio compared to control values. These findings suggest T cell activation in asthmatic cats similar to the findings in humans with asthma (Padrid et al., 1996, 1995b). In this experimental model we found that treatment with cyclosporine A (CsA) dramatically inhibited the pathologic changes in airway structure and function seen in cats not treated with CsA (Padrid, Cozzi, and Leff, 1996). (However, these findings should *not* be interpreted to mean that cyclosporine should be used to treat naturally occurring asthma in cats.) I have also shown that serotonin is a primary mediator in feline mast cells that contribute to airway smooth muscle contraction in vitro (Padrid et al., 1995a). This mediator is absent in human, equine, and canine airways. During an acute asthmatic attack, inhaled antigens within airways promote mast cell degranulation acutely with release of preformed serotonin. These mediators cause sudden contraction of airway smooth muscle. Interestingly, it has long been assumed that histamine released from feline mast cells caused acute bronchoconstriction. This assumption recently has been challenged by the finding that histamine nebulized into cat airways has an unpredictable effect from one cat to another. Specifically histamine may have no effect, it may cause bronchoconstriction, or it may actually dilate feline airways. These findings have potential therapeutic applications, as described later in the chapter.

Reinero and colleagues (2005) developed an experimental feline model in which cats were sensitized and chronically challenged with either Bermuda grass allergen (BGA) or house dust mites to mimic well-recognized antigenic triggers of human asthma. These cats produce allergen-specific immunoglobulin (Ig)E, allergen-specific serum and BAL fluid (BALF) IgG or IgA, airway hyperactivity, airway eosinophilia, an acute Th2 cytokine profile in peripheral blood mononuclear cells and BALF cells, and histologic evidence of airway remodeling. This model has been particularly helpful in evaluating specific immunomodulating treatment strategies. For example, cats sensitized and challenged with BGA to develop the asthmatic phenotype were then treated with rush immunotherapy (parenteral high doses of BGA). These cats had significantly reduced eosinophil counts. More recently Norris and associates (2003) used CpG motifs (microbial oligodeoxynucleotide products that modulate activity in human and murine lymphocytes) in cats with BGA-induced airway inflammation and hyperactivity. This approach dampened the eosinophilic response normally seen in these antigen sensitized and challenged cats; however, the hyperactivity within airways was not affected.

CLINICAL FINDINGS IN FELINE BRONCHITIS AND ASTHMA

Incidence and Prevalence

Currently there are no reliable data regarding the incidence and prevalence of asthma in cats. The prevalence of lower airway disease in the general adult cat population is estimated to be approximately 1%; prevalence in the Siamese breed may be 5% or greater. In 2000 a website (fritzthebrave.com) was developed to draw attention to the diagnosis and treatment of feline asthma. One result of this website was the generation of a "list-serve" with greater than 500 members, each of whom is the owner of one or more cats with asthma or bronchitis. A poll of these members revealed that more than 15% of the owners represented by this relatively random sample had Siamese cats (Kathryn Hopper, personal communication).

Clinical Signs

Clinical signs are variable. Cats with bronchitis have a daily cough and may be absolutely symptom free between episodes of cough. Alternatively they may be tachypneic at rest. Asthmatic cats may cough, wheeze, and struggle to breathe on a daily basis. In mild cases symptoms may be limited to occasional and brief coughing. Some cats with asthma may be asymptomatic between occasional episodes of acute airway obstruction. Severely affected cats may have a persistent daily cough and experience many episodes of life-threatening acute bronchoconstriction.

As previously outlined, a common problem for the practitioner is to distinguish between chronic bronchitis and asthma as the cause of a chronic cough in cats. Although these two disorders are frequently lumped together under the title of chronic bronchial disease or lower airway disease, the two disorders may require different therapeutic approaches and often have different prognoses. By definition all cats with chronic bronchitis have daily cough. Some cats with asthma may be asymptomatic between occasional episodes of acute airway obstruction. Other asthmatic cats may cough occasionally and demonstrate frequent tachypnea. Importantly, asthmatic cats but not bronchitic cats may benefit from bronchodilator treatment.

Physical Examination

There are no consistent physical examination findings on which to base a diagnosis of asthma. In fact, cats with bronchitis or asthma may have a normal physical examination at rest. Conversely, respiratory distress primarily during expiration is the hallmark of these disorders in cats. Adventitious sounds, including crackles, often are heard. Wheezes are more characteristic of feline asthma.

DIAGNOSTIC TESTS

Thoracic Radiographs

Routine survey chest radiographs may be normal and should not cause the practitioner to abandon the diagnosis of

asthma. However, frequently radiographs may demonstrate diffuse prominent bronchial markings consistent with inflammatory airways. Radiographic signs of increased lung lucency and flattening and caudal displacement of the diaphragm represent hyperinflation and suggest air trapping. In my experience approximately 10% of chest radiographs of cats with bronchial disease have increased density within the right middle lung lobe associated with a mediastinal shift to the right. This is evidence of atelectasis. In more extreme cases fluffy, ill-defined heavy interstitial infiltrates in multiple lung lobes may be appreciated. The cause of these changes in cats with lower airway disease may be multiple small areas of atelectasis in multiple lung lobes resulting from multiple diffuse small mucous plugs. This presents a diagnostic challenge because this radiographic change is consistent with a number of disorders, including neoplasia and diffuse interstitial pneumonitis.

Bronchoscopy

I emphasize that bronchoscopy is rarely required to make an accurate diagnosis of bronchitis or asthma in feline patients. Bronchoscopy in healthy cats is not a trivial undertaking. In cats with cough and respiratory compromise bronchoscopy may be a life-threatening procedure and should only be performed by persons adequately and formally trained in the technique (Johnson and Drazenovich, 2007). Instead the previously described historical and physical examination findings and results of chest radiography are sufficient to make a *tentative* diagnosis. *Definitive* diagnosis usually can be made in these patients by a strongly positive response to therapy. In fact, in my experience the primary indication for bronchoscopy in these patients occurs when there is not an otherwise predictable cessation or minimization of clinical signs after 6 to 7 days of aggressive corticosteroid treatment.

Tracheobronchial Culture

The presence of a mixed population of aerobic bacteria in airways has been reported previously in cats with bronchial disease. However, neither the lower airway nor the lung parenchyma of healthy cats is sterile. Organisms usually considered as pathogens such as *Klebsiella* and *Pseudomonas* spp. can be recovered from healthy feline airways. To my knowledge studies designed to correlate the clinical status of asthmatic or bronchitic cats with the presence or absence of bacteria within the airway have not been attempted or published. In fact, one well-designed study showed that cats with signs of bronchial disease had fewer positive airway cultures than a cohort population of healthy cats (Dye et al., 1996).

It is my experience that bacteria isolated from the asthmatic or bronchitic feline airway most commonly reflect colonization rather than true infection. The role of *Mycoplasma* may be an exception to this (Chandler and Lappin, 2002). *Mycoplasma* (and certain viruses) can degrade neutral endopeptidase, which is an enzyme that is responsible for biodegradation of substance P, a protein capable of causing bronchoconstriction and edema in the

feline airway. *Mycoplasma* might then indirectly prolong the effects of substance P on airway smooth muscle. It is tempting to speculate that *Mycoplasma* or viruses such as herpes, which can remain dormant in feline airways, might be responsible for increasing the levels of substance P in cat airways and contribute to spontaneous bronchoconstriction.

Tracheobronchial Cytology

Until the 1980s it was generally assumed that eosinophils played only a beneficial role in the immune system by protecting against parasite infestation. However, within the last 20 years it has become clear that the presence of these cells in the wrong place at the wrong time can result in significant cellular and tissue damage. Therefore it is of great interest that eosinophils (often 20% to 25% of total count) can be recovered in large numbers from the tracheobronchial washings of many healthy cats (Padrid, 1991). These cells appear to cause no damage to the local tissue environment, and their presence should not be assumed to indicate allergy or parasitism. Similarly, alveolar macrophages are a normal cell within the lung parenchyma and are the most common cells recovered from BALF obtained from healthy cats. These cells do not reliably represent granulomatous or histiocytic inflammation when obtained in BAL from bronchitic or asthmatic cats.

Consistent with prior remarks regarding the role of bronchoscopy in the diagnosis of feline bronchial disease, I do not routinely collect tracheobronchial washings to make the diagnosis of asthma or bronchitis in felines. These diagnoses are made by careful history taking, physical examination findings, radiographic interpretation, and response to therapy. It is only when these criteria are not fulfilled, and especially if the patient does not respond to standard treatment protocols, that the diagnosis is revisited and bronchoscopy/tracheal washings are considered. Although some clinicians do prefer to obtain airway washings and culture before initiation of long-term respiratory therapy, the points made previously should be considered when interpreting the cytologic picture or culture results.

TREATMENT OF BRONCHITIS AND ASTHMA IN CATS

The primary signs of asthma include cough and wheeze, and these signs are frequently the result of some degree of airway smooth muscle contraction. In clinical practice it is usually difficult to distinguish between chronic bronchitis and asthma in feline patients. It is tempting to treat coughing cats with suspected bronchial disease by using only bronchodilators to relax the airway smooth muscle contraction. Although this is a central method of treatment when acute signs develop, it is critically important to understand that human (and perhaps feline) asthmatic and bronchitic airways show evidence of chronic ongoing inflammation whether the patient is symptomatic or not. Therefore treatment strategies are most successful if they are directed toward *decreasing the underlying inflammatory component* of the disease in addition to addressing the acute clinical signs of cough, wheeze, and increased respiratory effort.

Long-Term Corticosteroids

The most effective long-term treatment of chronic non-infectious bronchial disease is systemically administered corticosteroids. This class of drugs is most likely to suppress airway inflammation, a process orchestrated by a network of proteins (cytokines) that act on circulating and structural airway cells. An important effect of steroids is to inhibit the synthesis of genes for cytokines that are important in generating airway inflammation.

The side effects of these medications given for long periods are undesirable. Fortunately inhaled steroids have become available that do not cause systemic side effects, and this therapeutic approach has greatly enhanced our ability to treat patients with bronchial disease (see Aerosol Delivery of Steroids and Bronchodilators later in the chapter). I begin treatment of bronchitic or asthmatic cats with signs that occur more than once weekly (without medication) with prednisolone, 1 to 2 mg/kg orally every 12 hours for 5 to 7 days. At this point most newly diagnosed cats have greatly diminished signs. The dosage of steroids is then tapered slowly, over at least 2 to 3 months. This approach is much more effective than giving low doses of prednisone for short periods and in response to acute flare-ups.

Patients with symptoms that occur less than once weekly (without medication) are generally not considered to have chronic active inflammatory airways. These patients may be treated safely with bronchodilators when needed.

Some cats are managed effectively and safely by administration of low-dose, alternate-day corticosteroids. However, most cats with chronic bronchial disease continue to wheeze/cough when treated in this conservative manner. For patients with a positive response to higher doses of consistently administered systemic corticosteroids, inhaled corticosteroid therapy should be encouraged as an alternative to reduce adverse effects (see Aerosol Delivery of Steroids and Bronchodilators later in the chapter).

Injectable Steroids

Parenteral administration of long-acting corticosteroids is limited to patients for whom no other method of drug administration is feasible. In this setting injection of methylprednisolone (Depo Medrol, Phizer Animal Health, 10 to 20 mg IM total dose) once every 4 to 8 weeks may be effective. This therapy is very likely to result in significant/serious side effects, including weight gain, diabetes mellitus, and reduced immunity and represents the treatment of last resort.

Bronchodilators

The use of bronchodilators is based on the assumption that clinically significant bronchoconstriction is evident. Cats develop naturally occurring and clinically significant bronchoconstriction that in severe cases can be life threatening (Padrid, 2000). Bronchodilator drugs can be beneficial to these patients. These drugs are classified generally as β -receptor agonists, methylxanthine derivatives, or anticholinergics.

Most adrenergic agonists have variable α - and β -receptor affinity. Nonselective β -receptor agonists such as isoproterenol or mixed α - and β -receptor agonists such as epinephrine are more likely to produce cardiovascular side effects than similarly administered selective β -agonists. Consequently drugs with preferential affinity for β_2 -receptors are likely to provide more effective bronchodilation with fewer side effects. The two principal β_2 -agonists currently marketed in preparations that can be readily and regularly used in small animals are terbutaline sulfate and albuterol sulfate. A discussion of these drugs follows.

Terbutaline Sulfate

Terbutaline is a selective β_2 -receptor agonist that produces relaxation of the smooth muscle found principally in bronchial, vascular, and uterine tissues. The exact mechanism by which activation of β_2 -receptors results in smooth muscle relaxation is not totally understood, but it likely involves intracellular cyclic adenosine monophosphate-induced suppression of the kinase controlling myosin and actin interaction.

Terbutaline is available as a tablet, elixir, and injectable preparation suitable for subcutaneous or intramuscular use. The dosage rate has been reported to range from 0.01 mg/kg given subcutaneously or intramuscularly up to 0.1 to 0.2 mg/kg every 8 hours given by mouth. The *major clinical indication* for terbutaline is treatment of the patient with acute respiratory difficulty when inhaled albuterol therapy is not possible. Infrequently terbutaline is prescribed as a chronic oral treatment for bronchodilation.

Many veterinarians use terbutaline as an emergency drug to treat asthmatic cats that present in respiratory distress. The drug is similarly effective in humans. The home use of a rapid-acting bronchodilator such as inhaled albuterol or injected terbutaline can preclude the need for a stressful emergency room visit. I teach my clients to use an inhaler (see Aerosol Delivery of Steroids and Bronchodilators later in the chapter) or to administer terbutaline subcutaneously to their asthmatic cats at a dose of 0.01 mg/kg subcutaneously or intramuscularly. An obvious beneficial response generally occurs within 15 to 30 minutes. This may be repeated if a significant benefit is not observed after one dose. To determine if the drug has been absorbed and if a beneficial effect has occurred, heart rate and respiratory rate and effort are monitored before drug administration. A heart rate that approaches 240 beats/min suggests that the drug has been absorbed. A respiratory rate or effort (or both) that declines by 50% or more suggests a beneficial effect.

At usual doses terbutaline has little effect on β_1 -receptors; thus direct cardiostimulatory effects are unlikely. However, terbutaline should always be used with care in patients that may have increased sensitivity to adrenergic agents—in particular cats with preexisting cardiac disease, diabetes mellitus, hyperthyroidism, hypertension, or seizure disorders. All β_2 -agonists may lower plasma potassium; thus in at-risk patients receiving long-term terbutaline therapy, it may be prudent to monitor serum potassium levels. In clinical practice and experimentally it is rare to find β_2 agonist-associated hypokalemia in cats (Petruska et al., 1997). When terbutaline is used with other sympathomimetics or concurrently with digoxin,

tricyclic antidepressants, and monoamine oxidase inhibitors, the risk of adverse cardiovascular effects increases. These potential effects are more likely in patients with preexisting cardiac disease, especially hypertrophic cardiomyopathy. Use with various inhalation anesthetics may predispose the patients to ventricular arrhythmias.

Albuterol Sulfate

Albuterol is a selective β_2 -receptor agonist with pharmacologic properties similar to those of terbutaline. Albuterol is available as a tablet and syrup and is contained in various inhalants. I have only used the inhaled form of albuterol in feline patients. The inhaled form of albuterol comes as a single-strength 17g metered-dose inhaler (MDI) and delivers 90mcg per actuation of the device.

The pharmacokinetic profile of albuterol in cats has not been reported. When administered by inhalation to humans, albuterol produces significant bronchodilation within 15 minutes that lasts for 3 to 4 hours. It is also well absorbed orally and may have bronchodilatory effects for up to 8 hours. Anecdotal experience with this drug in clinical practice suggests a similar pharmacokinetic profile in cats. Albuterol undergoes extensive hepatic metabolism. After oral administration approximately 58% to 78% of the dose is excreted in the urine over 24 hours, with 60% of the drug in an inactive form.

Rarely adverse effects include mild skeletal muscle tremors and restlessness, which generally subside after 2 to 3 days. As with terbutaline, care should be exercised when administering albuterol to patients with preexisting cardiac disease, diabetes mellitus, hyperthyroidism, hypertension, and seizure disorders. Potential drug interactions are similar to those of terbutaline.

Methylxanthines: Theophylline and Aminophylline

The methylxanthines relax smooth muscle, particularly bronchial smooth muscle, stimulate the central nervous system (CNS), and act as a weak cardiac stimulant and diuretic. Although I do not use this class of drugs to treat feline patients with asthma, methylxanthines are used frequently in the veterinary profession and thus are addressed briefly.

Theophylline is considered a less potent bronchodilator than the β -agonists (Bjerner, 2001). It has been shown in other species to produce centrally mediated increased respiratory effort for any given alveolar P_{CO_2} ; to improve diaphragmatic contractility with reduced diaphragmatic fatigue; to mildly increase myocardial contractility and heart rate; and to increase CNS activity, gastric acid secretion, and urine output. All of these effects have not been demonstrated in cats. Interestingly, at therapeutic concentrations of theophylline only adenosine receptor blockade has been reliably demonstrated. This has been suggested to explain the varied effects of theophylline.

Because of the relatively low therapeutic index and pharmacokinetic characteristics of theophylline, dosage rates should be based on lean body mass. The dosage depends on the preparation used. In standard preparations the recommended dosage for cats is 4 mg/kg every 8 to 12 hours. When using sustained-release preparations a dosage of 25 mg/kg every 24 hours should be considered.

The pharmacokinetics of theophylline have been studied extensively in a number of species (Boothe, 2006). After oral administration, peak plasma rates occur within 1.5 hours. The rate of absorption is limited principally by dissolution of the dosage form in the gut. Bioavailability in cats is generally greater than 90% when nonsustained-release preparations are used; however, sustained-release preparations may have a more variable bioavailability. In general the anhydrous theophylline tablet is preferred. A chronopharmacokinetic study in cats showed that evening administration is associated with better bioavailability and less fluctuation in plasma drug level (Dye et al., 1990).

Although theophylline can produce CNS stimulation and gastrointestinal disturbances, these effects are most often associated with excessive dosing and resolve with dosage adjustments. Seizures or cardiac arrhythmias may occur in severe toxicity. There are a number of known drug interactions with theophylline, including enrofloxacin (Baytril). The effects of theophylline may be diminished by phenytoin or phenobarbital and enhanced by cimetidine, allopurinol, clindamycin, and lincomycin. The effects of theophylline and β -adrenergic blockers may be antagonized if they are administered concurrently. Theophylline increases the likelihood of arrhythmias induced by adrenergic agonists and halothane and the likelihood of seizures with ketamine.

Antibiotics

There is no objective evidence that bacterial infection plays a significant role in the cause or continuation of feline chronic bronchitis or asthma. Similarly there is no objective evidence that antibiotic therapy has any effect on the duration or intensity of signs displayed by the cat with chronic bronchial disease. It is important to remember that the clinical signs of asthma in cats frequently wax and wane both in severity and in frequency of occurrence. Many anecdotal reports describe the therapeutic effect of antibiotics in controlling asthmatic symptoms, but these reports are consistent with the "waxing and waning" nature of the symptom in nontreated cases.

A positive culture result obtained from a tracheobronchial wash does not necessarily imply the presence of a clinically significant airway infection and should not automatically prompt the clinician to initiate antibiotic therapy. In my opinion antibiotics are rarely indicated for cats with chronic bronchitis or asthma and are appropriate only when there is strong evidence of superimposed airway infection. This may be inferred from the growth of a pure bacterial culture on a primary culture plate from material obtained from tracheobronchial secretions because the concentration of aerobic bacteria recovered from the airways of healthy cats rarely exceeds 5×10^3 organisms per milliliter. In contrast, growth of a single organism recovered without the use of enrichment broth implies more than 10^5 organisms per milliliter, and this is consistent with an infected airway in humans. Antibiotic therapy is then based on sensitivity data. Prophylactic or long-term therapy should be avoided unless there is documentation of a chronic airway infection, which is uncommon.

One possible exception to these statements involves *Mycoplasma* spp. *Mycoplasma* has been isolated from the airway of as many as 25% of cats with signs of lower airway disease, but it has not been cultured from the airway of healthy cats. For this reason and because it has the potential to cause significant structural damage to airway epithelium, it may be prudent to treat any cat with a *Mycoplasma*-positive airway culture with an appropriate antibiotic such as doxycycline or azithromycin.

Cyproheptadine

Cyproheptadine (Periactin, Merck Sharp and Dohme) is marketed as an antihistamine; however, it has been used for years as an appetite stimulant for depressed or anorectic cats because of its antiserotonin properties. As mentioned earlier, serotonin is a primary mediator released from activated mast cells into feline airways and causes acute smooth muscle contraction (bronchoconstriction) in cats but not in humans. I have shown that the ability of cyproheptadine to block serotonin receptors in muscle cells is effective in preventing antigen-induced airway smooth muscle constriction in vitro. Limited clinical observations in asthmatic cats have supported these in vitro findings. The primary indication for this drug is a trial in the symptomatic asthmatic cat already receiving maximal doses of terbutaline and corticosteroids. Cyproheptadine comes in both pill and liquid form and is dosed at 2 to 4 mg orally every 12 hours (Boothe, 2006). A beneficial therapeutic response may not be seen for 4 to 7 days; but depression, the primary side effect of this drug, may be observed 24 hours after administration. Depression is not life threatening but may cause the owner to discontinue cyproheptadine therapy.

Antileukotrienes: Zafirlukast, Montelukast, and Zileuton

Leukotrienes belong to a family of inflammatory mediators that are derived from arachidonic acid and are known collectively as eicosanoids. The leukotrienes LTC₄, LTD₄, and LTE₄ collectively are known as the cysteinyl leukotrienes and play an important role in airway inflammation. They produce mucus hypersecretion, increased vascular permeability, and mucosal edema; induce potent bronchoconstriction; and act as chemoattractants to inflammatory cells, particularly eosinophils and neutrophils.

The orally administered antileukotriene drugs are competitive, highly selective, and potent inhibitors of the production or the function of LTC₄, LTD₄, and LTE₄. Specifically, zileuton (Zyflo, Abbott Laboratories) blocks leukotriene biosynthesis by inhibiting production of the 5-lipoxygenase enzyme, whereas both montelukast and zafirlukast block adhesion of leukotrienes to their common leukotriene receptor (cys-LT1). In humans leukotrienes inhibit asthmatic responses to allergen, aspirin, exercise, and cold dry air. In addition, leukotriene blockade has been shown in many clinical trials to decrease the amount and frequency of administration of corticosteroids in steroid-dependent human asthmatics.

There have been few investigations regarding the role of leukotrienes in feline airway disease. Although LTE₄ is

found in increased concentrations in urine of asthmatic humans, no such increase in urinary LTE₄ was found in 20 cats with signs of bronchial disease or in cats with experimentally induced asthma in unpublished studies that I conducted (1995) (Mellema, 1998). More recently in another experimental model of feline asthma, no increase in cysteinyl leukotrienes was found in either urine or BALF after challenge exposure to sensitizing antigen (Norris et al., 2003). In addition, zafirlukast did not inhibit airway inflammation or airway hyperreactivity in this feline asthma model (Reinero et al., 2005). Thus there is no current evidence that drugs that affect leukotriene synthesis or receptor ligation play a significant role in the treatment of feline or canine respiratory disease. However, there is at least one claim of efficacy using zafirlukast (1 to 2 mg/kg BID) or montelukast (0.5 to 1 mg/kg SID) for treatment of feline asthma (Mandelker and Padrid, 2000).

Aerosol Delivery of Steroids and Bronchodilators

Aerosol administration of the corticosteroid fluticasone and the bronchodilator albuterol rely on delivery of drug to the distal airways, which in turn depends on the size of the aerosol particles and various respiratory parameters such as tidal volume and inspiratory flow rate. Even in cooperative humans only approximately 10% to 30% of the inhaled dose enters the lungs. Recent studies in cats have demonstrated that passive inhalation through a spacer-mask combination (Aerokat, Aerokat Trudell Medical International, Inc.) is an effective method of delivering sufficient medication to be clinically effective (Reinero et al., 2005; Kirchvink et al., 2006).

Drugs for inhalation typically come in a rectangular MDI or a round "diskus" form. At the present time only the MDI form is practical for use in animals. Recently the propellants used for these medications have changed. The most effective means of using an MDI involves coordination between inhalation and actuation of the device, something that is not reliable in most infants, small children, or animals. For this reason an alternative involves the use of a spacer device and a mask specifically designed for cats (Fig. 148-1). A small, aerosol-holding chamber is attached to an MDI on one end and a face mask on the other. The spacer is approximately the size of the inner cardboard roll used with toilet paper. The MDI supplies precise doses of the aerosol drug, and the holding chamber contains the aerosol so it can be inhaled when the patients inspires. The mask is designed to cover the nose of the cat. The designers of the Aerokat spacer have shown that a holding chamber with a length of 11 cm and a diameter of 3.5 cm or larger delivered almost all of a therapeutically "ideal" aerosol (i.e., aerosol of equivalent aerodynamic diameter $\leq 2.8 \mu\text{m}$) produced by an MDI; and in some cases delivery was enhanced because of evaporation of large, suspended particles (Foley, personal communication). The choice of spacer is relevant because cats have a tidal volume of between 5 to 10 ml of inspired air per pound of body weight. Currently only the Aerokat brand spacers have been designed specifically based on the tidal volume characteristics of the cat. Using these spacer devices, cats

Fig. 148-1 The AeroKat spacer is specifically made for the feline species. The MDI fits snugly on one end, and the mask fits comfortably on the patient's nose. A float valve is built into the front of the spacer to let the owner know when the patient takes a breath.

inhale the majority of drug propelled into the spacer by breathing 7 to 10 times through the spacer-mask combination after actuation of the MDI. It is important to teach the owner to observe the pet actually breathing because cats initially may hold their breaths when introduced to this form of treatment.

The procedure is not time-consuming, but it can be helpful to acclimate the cat to the mask. When administering inhalation therapy, the MDI is first shaken to open an internal valve within the canister, and then it is attached to the spacer. The mask attached to the other end of the spacer is placed snugly on the animal's nose or muzzle, and the MDI is pressed to release the medication into the spacer.

Fluticasone Propionate

The most commonly used inhaled corticosteroid is fluticasone propionate (Flovent, GlaxoSmithKline), a synthetic corticosteroid with an 18-fold higher affinity for the corticosteroid receptor when compared to dexamethasone. Binding of the steroid to this receptor results in a new molecular complex that leads to up- or down-regulation of the gene and its products. Like other corticosteroids, fluticasone acts to inhibit mast cells, eosinophils, lymphocytes, neutrophils, and macrophages involved in the generation and exacerbation of allergic airway inflammation by transcriptional regulation of these target genes. Preformed and newly secreted mediators, including histamine, eicosanoids, leukotrienes and multiple cytokines, are inhibited as well.

Fluticasone is a large molecule and acts topically within the airway mucosa. Because there is poor absorption across gut epithelium, there is minimal oral systemic bioavailability. Plasma levels do not predict therapeutic effects. This explains the lack of systemic side effects; however, it also suggests that clinically effective absorption into the airway mucosa is also delayed. Therefore optimal clinical effects may not occur for 1 to 2 weeks.

Fluticasone has been used to treat cats with bronchial asthma at least since 1993. Since then a number of manuscripts have demonstrated the clinical effectiveness of fluticasone for treatment of cats with allergic rhinitis, bronchitis, and asthma (both naturally occurring and experimentally induced). There have been no controlled published studies to determine the optimal dose or interval for use of fluticasone in cats; however, there are anecdotal reports that reference more than 500 small animal patients treated with fluticasone over a period covering 1995 through 2006. Dosage recommendations are based on these observations and recently published studies.

Fluticasone comes in three strengths: 44 mcg, 110 mcg, and 220 mcg per actuation. I have found that 44-mcg dosing twice daily does not consistently result in acceptable clinical responses. For cats with mild-to-moderate disease, 110 mcg given twice daily frequently results in clinical responses equivalent to that achieved by administration of 5-mg oral doses of prednisone given BID. Cats with more serious disease may require 220 mcg inhaled BID. In my experience administration of fluticasone more than twice daily has not resulted in clinical benefit.

Albuterol Sulfate

The pharmacology of albuterol, a selective β_2 -adrenergic bronchodilator, has been described previously. This drug is available through different manufacturers and is commonly prescribed as Ventolin (GlaxoSmithKline) or Proventil (Schering Corp.). Albuterol only comes in a single uniform strength (90 mcg per inhalation). Albuterol usually results in relaxation of airway smooth muscles within 1 to 5 minutes; thus the effect is almost immediate. This drug should be used in animals with documented or assumed bronchoconstriction. Symptoms that may indicate bronchoconstriction are wheeze, noisy lower airway breathing, prolonged expiratory phase of ventilation, and coughing. Albuterol can be used once daily before administering fluticasone or as needed for acute coughing and wheezing. In emergency cases albuterol can be used every 30 minutes for up to 4 to 6 hours without serious side effects.

The use of inhaled medications to treat asthma and bronchitis is considered the standard of care in humans and is now widely recommended for cats with chronic bronchial disease. This approach avoids many of the side effects previously seen in patients treated with systemic medications.

CHAPTER 149

Bacterial Pneumonia

RICHARD B. FORD, *Raleigh, North Carolina*

Acquired inflammatory lung disease associated with bacterial colonization of tissues in the lower respiratory tract (lower airways and lung parenchyma) constitutes a clinical definition of bacterial pneumonia. Bacterial pneumonia occurs with moderate frequency in dogs but is considerably less common in cats. Ranking as one of the most complex life-threatening infections encountered in companion animal practice, bacterial pneumonia poses significant diagnostic and therapeutic challenges to the clinician.

INFECTION OF THE LOWER AIRWAYS AND LUNG

Complicating basic research into the pathogenesis of lung infection is the fact that experimentally induced

bacterial pneumonia in healthy animals is difficult to achieve. In normal adult animals the oral cavity, the upper respiratory tract, and trachea are host to a variety of pathogenic bacteria, yet the ability of these pathogens to actually infect is limited by exceptionally effective host defenses unique to the lower respiratory tract. This suggests that other underlying mechanisms must work collectively to the point of causing airway or lung injury with subsequent bacterial colonization of airway epithelium or interstitial cells of the lung. The nature of bacterial infection and lower respiratory tract injury is complex.

The mere presence of bacteria in lower airways does not define bacterial pneumonia. In healthy dogs and cats resident bacteria from the oral-nasal cavity can be recovered from respiratory epithelium as far into the respiratory

tract as the carina. For bacteria to actually infect the lung parenchyma, colonization must occur. This requires that organisms have access to a portal of entry. The larynx and trachea represent the most common portal for lower respiratory tract infections, but a second portal of entry to the respiratory tract is via hematogenous dissemination of bacteria from a point of distant infection. Bacterial pneumonia in dogs results predominantly from bacteria that enter via the larynx and trachea. Bacterial pneumonia in cats is poorly described in the literature. Most authors would agree that bacterial lung infections occur much less often in cats than in dogs; however, hematogenous dissemination of pathogenic bacteria leading to bacterial pneumonia actually may occur more often in cats than in dogs (Foster et al., 2004).

Subsequent to colonization, bacterial adherence must occur. This entails a complementary and specific interaction between receptors on the epithelial cell surface and macromolecules on the cell wall surface of bacteria called *adhesins*. *Bordetella bronchiseptica*, a common pathogen recovered from dogs and cats with bacterial pneumonia, expresses a common set of secreted and surface-associated adhesins such as filamentous hemagglutinin, fimbriae, and periactin that significantly influence colonization and virulence.

Extracellular proteins called *invasins* are produced by bacteria and act to break down host defenses and facilitate the spread of bacteria. Unique to the invading pathogen, these proteins serve as “spreading factors” (hyaluronidase, collagenase, and streptokinase). Other types of *invasins*, sometimes called exotoxins, cause direct injury to cell membranes, leading to cell lysis (hemolysins, leukocidins, streptolysin).

Pathogenic bacteria that are successful in their attempt to infect the patient possess structural or biochemical features that enable them to resist host defense mechanisms, specifically phagocytosis and adaptive immune responses (humoral and cell-mediated immunity). Specific to individual bacterial species are soluble proteins (toxins) secreted during periods of exponential growth. Bacterial toxins are highly specific in their action but are inherently unstable. Over time these proteins lose their toxic properties but retain antigen properties, as evidenced by their use in some vaccines. The activity of bacterial toxins has considerable influence on the virulence of the organism, the onset of clinical illness, the severity of infection, and even the prognosis.

RISK FACTORS

In addition to intrinsic virulence factors associated with individual bacterial pathogens, compromised host defenses play a critical role in an individual's risk of acquiring bacterial pneumonia. Increased age, underlying systemic illness, compromised immunity, and poor nutrition are often cited. However, these are largely intangible factors that are difficult to quantify and offer little predictive value in the clinical setting. In my experience young dogs and cats, in contrast to older animals, are at greatest risk of developing bacterial pneumonia. Critical factors contributing to morbidity include immunization status,

congenital disorders (megaesophagus, ciliary dyskinesia), environment (especially housing, sanitation, and ventilation), exposure to clusters of dogs, and coinfection (e.g., calicivirus infection in kittens or canine distemper virus in puppies). Aspiration pneumonia, commonly associated with acquired megaesophagus, myasthenia gravis, and laryngeal paralysis, is perhaps the single most common cause of bacterial pneumonia seen in adult dogs. Systemic or local bacterial infection (e.g., bacteremia, phlebitis, or periodontitis) is also a predisposing risk factor for bacterial pneumonia.

TYPES OF BACTERIA

Several studies have reported on the types of bacteria isolated from dogs and cats with bacterial pneumonia. These findings are summarized in Box 149-1. Gram-positive and gram-negative aerobes are commonly reported. Anaerobic infections, typically recovered in patients coinfecting with either enteric or staphylococcal infections, do occur but are less frequently reported. Most *Mycoplasma* isolates recovered from the airways of animals have been found to coexist with other bacteria. Limited reports involving both dogs and cats with evidence of lower respiratory tract disease have identified *Mycoplasma* spp. as the sole bacterial isolate (Chandler and Lappin, 2002). Although the precise role of *Mycoplasma* spp. as a primary pathogen in bacterial pneumonia in dogs and cats requires further definition, some clinicians request culture for *mycoplasma* on separate media when attempting bacterial isolation from airway washings.

Bacterial pneumonia that develops subsequent to aspiration of gastric contents or opportunistic infections is more likely to be associated with gram-negative bacteria. However, from the available literature it is not possible to establish true prevalence of one bacterial pathogen over another as a causative agent in bacterial pneumonia. The most commonly reported gram-positive bacteria include *Staphylococcus*, *Streptococcus*, and *Enterococcus* spp. Among the gram-negative bacterial isolates, *B. bronchiseptica* and *Pasteurella* are the most frequently reported

Box 149-1

Pathogens Commonly Associated With Bacterial Pneumonia in Dogs and Cats

Canine

- *Bordetella bronchiseptica*
- *Staphylococcus* spp.
- *Streptococcus* spp.
- *Enterococcus* spp.
- *Escherichia coli*
- *Pseudomonas* spp.
- *Pasteurella* spp.
- *Klebsiella* spp.
- *Bacteroides*

Feline

- *Pasteurella* spp.
- *Bordetella bronchiseptica*
- *Streptococcus equi* spp.
- *zooepidemicus*
- *Pseudomonas* spp.
- *Mycoplasma* spp.

(Brady, 2004). A recent study into the cause of community-acquired infectious pneumonia among dogs under 1 year of age showed *B. bronchiseptica* to be the predominant bacterium recovered (at 49%) (Radhakrishnan et al., 2007). In several studies *B. bronchiseptica* has been cited as a predominant cause of bacterial pneumonia in dogs and cats. In dogs under 1 year of age, clinical disease caused by *B. bronchiseptica* pneumonia was determined to be more severe than pneumonia caused by other types of bacteria (Radhakrishnan et al., 2007).

DIAGNOSIS

The diagnosis of bacterial pneumonia generally is based on information derived from the history, physical examination findings, and thoracic radiography. However, in cats the clinical manifestation of bacterial pneumonia is quite different from that of the dog. Clinical findings characteristic of pneumonia in dogs can be completely absent in cats with active bacterial pneumonia.

Clinical History

The chief complaint associated with bacterial pneumonia does not routinely include cough, although this sign should prompt consideration of bronchopulmonary infection. Dogs and cats may be lethargic and have decreased exercise tolerance or interest in playing, inappetence, increased respiratory rate or effort, or persistent nasal discharge. Regurgitation related to esophageal disease, vomiting, and audible wheezing (as with laryngeal paralysis) are commonly reported findings in dogs with aspiration pneumonia. In contrast, owners of cats with pneumonia may not have observed any abnormal respiratory pattern or nasal discharge. Hospital-acquired pneumonia in both species has been associated with general anesthesia, administration of opiates, or lack of consciousness.

Physical Examination

Increased respiratory rate at rest and fever are anticipated but also inconsistent physical findings in patients with bacterial pneumonia. Cough, if present, may or may not be elicited on manipulation of the cervical trachea. Evidence of a purulent nasal and ocular discharge in a lethargic patient certainly warrants further assessment for lower respiratory disease.

Careful auscultation can be quite revealing. Evidence of fluid (mucus) in the airways during normal respiration and especially during cough supports a diagnosis of bacterial pneumonia. However, either the absence of normal breath sounds or a marked asymmetry in left- versus right-sided breath sounds is an additional clinical finding that supports a diagnosis of bacterial pneumonia with lobar consolidation.

Radiology

Historical signs, physical examination findings, and other signs of inflammation (fever, elevated white blood cell count) may be suggestive of bacterial pneumonia; but thoracic radiography is fundamental to establishing the diagnosis

in both dogs and cats. Unless the patient is unable to be positioned, ventrodorsal and lateral projections are essential. In some patients obtaining both right and left lateral thoracic radiographs may be useful in assessing the extent of disease and ruling out other disorders (e.g., neoplasia). Although the ability to demonstrate lesions on thoracic radiography is important in establishing a diagnosis of bacterial pneumonia, the absence of abnormalities in a thoracic radiograph does not completely rule out a diagnosis of pneumonia.

Radiographic features of bronchopneumonia are variable and can vary from a diffuse, bronchointerstitial lung pattern to partial or complete alveolar density to consolidation. The cranioventral aspects of lung are most often affected in descending bacterial pneumonia. Although radiographs in cats with pneumonia can demonstrate classic lobar signs, the findings are more variable. Multifocal, patchy interstitial and alveolar changes may be evident; and even large nodules similar to those observed with metastatic lung disease may be identified. In cases of hematogenous pneumonia in either species the chest films may show diffuse interstitial-to-alveolar change, probably related in part to permeability (noncardiogenic) pulmonary edema. The presence of air in the esophagus may simply indicate aerophagia, but persistent esophageal dilation may indicate an underlying esophageal disorder such as megaesophagus or myasthenia gravis.

Bacterial Isolation

Although results of culture and sensitivity testing of transtracheal, endotracheal, or bronchoalveolar airway washes provide the optimal guidance for treatment of bacterial pneumonia, it is recognized that many patients are treated empirically in clinical practice. There are a number of reasons for this, including the inherent risks associated with collecting culture specimens from animals with respiratory distress. Empiric therapy is probably more justified in first-time cases of pneumonia or when radiographs or clinical signs do not suggest life-threatening bacterial pneumonia. Even when airway cultures are obtained, initial empiric antibiotic therapy is needed because it takes time for bacteria to grow in culture.

However, if initial treatment efforts appear to fail, the clinician is obligated to pursue the underlying etiology of suspected pneumonia. Cytology, Gram stain, and culture of fluid collected from the lower respiratory tract may be critical for therapeutic success in cases of hospital-acquired infection, when empiric treatment is failing, and in patients with pneumonia caused by unanticipated microorganisms (e.g., *Mycoplasma* spp. or in pulmonary blastomycosis). Recent treatment with antimicrobials does not necessarily predict negative culture results, and attempts to isolate the causative bacteria from patients receiving an antibiotic are still justified.

Collection of lower airway secretions may be accomplished by a number of methods. Transtracheal aspiration, a technique that does not require general anesthesia, is a particularly useful procedure in medium- to large-breed dogs with a productive cough. In small dogs and in cats endotracheal washing or bronchoalveolar lavage collected with or without a bronchoscope is preferable. However, since the latter procedures require short-term general or intravenous anesthesia, additional risks are incurred.

These techniques are described in detail elsewhere (Ford and Mazzaferro, 2006). When oropharyngeal contamination is a concern, the airways can be cultured using both an airway lavage sample and a guarded culture brush, which is passed through an endotracheal tube or optimally by bronchoscopic guidance. A positive brush culture may help distinguish contaminants when multiple organisms are isolated from the lavage.

Collected specimens should be handled appropriately for bacterial culturing. Some laboratories prefer to isolate *Mycoplasma* spp. using separate media, and sample handling should be discussed in advance with laboratory personnel.

In addition to culture, specimens collected from the lower respiratory tract should be examined cytologically. Leukocytes with intracellular bacteria confirm a diagnosis of bacterial pneumonia. However, the absence of bacteria does not exclude a diagnosis of bacterial pneumonia. The presence of the large bacterium *Simonsiella* (Cytophagales, Simonsiellaceae) in the airway cytology indicates that oropharyngeal contents have been aspirated into the airway or that samples have been contaminated during the collection. This finding may influence interpretation of culture results. When bacteria are evident, Gram staining of the specimen may provide some initial guidance for antibiotic therapy.

Transthoracic fine-needle lung aspiration using a 25- or 27-gauge, 1.5-inch needle is an alternative technique for obtaining diagnostic samples for cytology and culture. Patients with diffuse lung disease are better candidates for this procedure than cases of focal lung disease when the procedure is performed “blindly.” Fine-needle aspiration of focal lung lesions is best accomplished under ultrasound or computed tomography guidance. However, neither technique ensures prevention of most common postaspiration complications, particularly pneumothorax.

TREATMENT

“The most important criterion for selection of an antibacterial is identification of the bacterial organism” (Greene and Reinero, 2006). However, antibiotic treatment generally is initiated in any patient suspected of having bacterial pneumonia, even in the absence of microbiologic diagnosis. The decision to initiate empiric antimicrobial therapy is justified when the risk associated with collecting adequate samples may further jeopardize the patient or when the time required to culture the offending organism represents a potentially life-threatening delay in managing the patient’s infection.

Antibiotic therapy is the first treatment consideration in managing any patient suspected of having bacterial pneumonia. Initial selection of drug is usually based on the patient’s overall health status. Oral antimicrobials such as trimethoprim/sulfonamide, doxycycline, cephalexin, or amoxicillin/clavulanate may be sufficient in the patient that has mild clinical disease, is still eating, and requires little to no supportive care. Oral antimicrobials, especially a liquid suspension, may be most practical when treating puppies or kittens, particularly when several animals from the same household are affected simultaneously. Adult patients with advanced disease benefit from intravenous administration of antibiotics and concurrent fluid therapy.

Simultaneous administration of two or more antibiotics to an individual patient is indicated in severely compromised patients, especially when bacterial susceptibility testing is not feasible. Table 149-1 summarizes recommendations for the empiric administration of antibiotics in cats and dogs suspected of having bacterial pneumonia.

There are no standard recommendations regarding treatment duration for patients with bacterial pneumonia. In puppies and kittens an effective antimicrobial may only need to be administered for 5 to 7 days. In mature patients with recurring signs of pneumonia associated with an underlying disorder such as megaesophagus, treatment periods may extend a month or longer. Generally the decision to discontinue antimicrobial therapy is based on the patient’s activity, appetite, and evidence of resolution of the pneumonia based on follow-up thoracic radiographs. Generally treatment is continued for 1 to 2 weeks following resolution of radiographic lesions.

Supportive Treatment

Inflammation, fever, and insensible fluid loss (panting) dictate the need to maintain the hydration status of a patient with bacterial pneumonia. Patients that become dehydrated may experience decreased mucociliary clearance and alveolar emptying. Intravenous fluid therapy must be monitored carefully in the patient with bacterial pneumonia with the objective of avoiding overhydration.

Table 149-1

Options for Empiric Treatment of Bacterial Pneumonia in Dogs and Cats

First-Choice Treatments (Uncomplicated Pneumonia)	Alternative Treatments (Severe Pneumonia With Complications)
Dogs	
Doxycycline: 5 mg/kg PO (suspension recommended for puppies) q12h	Enrofloxacin: 5 mg/kg PO q12h (use in puppies is restricted to life-threatening disease)
Trimethoprim/sulfonamide: 15 mg/kg PO or SQ q12h	Enrofloxacin: 5 mg/kg PO q12h <i>plus</i> Amoxicillin-clavulanate: 15 mg/kg PO q12h
Cephalexin: 22-44 mg/kg, PO q8h	Enrofloxacin: 5-10 mg/kg IV q12h <i>plus</i> Imipenem-cilastatin: 3-10 mg/kg IV q8h Chloramphenicol: 50 mg/kg PO or IV or SQ q6h
Cats	
Azithromycin: 5-10 mg/kg PO once daily	Clindamycin: 10-15 mg/kg, PO q12h
Amoxicillin-clavulanate: 15 mg/kg PO q12h	Chloramphenicol: 50 mg (total) PO or IV q12h
Cephalexin: 22-44 mg/kg PO q8h	Ticarcillin-clavulanate: 30-50 mg/kg IV q8h
Trimethoprim/sulfonamide: 15 mg/kg PO or SQ q12h	

IV, Intravenously; PO, orally; SQ, subcutaneously.

This is critical in patients with diffuse pulmonary infection in which increased pulmonary capillary permeability may be present. In most patients fluids should be administered at maintenance rates only. Higher than maintenance rates of administration may cause fluid overload and further compromise lung function.

Administration of a bronchodilator to a patient with bacterial pneumonia is controversial. Both methylxanthine (theophylline salts) and β -agonist bronchodilators (terbutaline, albuterol) have been administered as supplemental treatments in patients with bacterial pneumonia. The purported benefits of bronchodilator therapy include increased airflow, improved ciliary activity, increased serous component of bronchial secretions, inhibition of mast cell degranulation, and decreased microvascular "leak." Diaphragmatic muscle strength also may be enhanced by methylxanthines.

Use of a mucolytic drug such as *N*-acetylcysteine is rarely indicated in the treatment of bacterial pneumonia in dogs and cats. Despite the antioxidant effects and possible benefits in patients with pulmonary fibrosis, *N*-acetylcysteine administered by aerosol or direct inoculation into the trachea is an irritant and may cause reflex bronchoconstriction.

Nebulization of saline, 10 to 15 ml, administered over 15 to 20 minutes two to three times daily appears to provide relief to patients with bacterial pneumonia and may facilitate clearance of secretions accumulated in the lower airways. Some patients with pneumonia seem to respond to humidification of the air, particularly in arid climates. Although not a substitute for systemic antimicrobial therapy, antibiotics also can be administered by nebulization in cases in which such treatment might be beneficial (e.g., in resistant canine bordetellosis). Such treatment has been used in children for resistant respiratory infections with variable results. Drugs used in nebulization generally are those that are poorly absorbed from the respiratory mucosa and that generally would not be administered systemically because of risk of systemic toxicity. Examples include gentamicin (50 mg in 5 ml of saline twice daily), kanamycin (250 mg in 5 ml of saline nebulized twice daily), and polymyxin B (333,000 units in 5 ml of saline twice daily). Small particle size (0.5 to 3 μ m) of nebulized fluids is critical for effective delivery of drugs or fluids into the lower respiratory tract. The use of a vaporizer or humidifier to deliver drugs is not effective. Pretreatment with inhaled albuterol may reduce irritation and attendant bronchial constriction.

Hypoxemia requiring administration of supplemental oxygen can develop in patients with severe pneumonia. Mechanisms for this functional disturbance include ventilation-perfusion inequality, arteriovenous shunting, and possibly diffusion impairment. Oxygen therapy is indicated in patients with a PaO_2 less than 85 mm Hg (or arterial oxygen saturation of less than 90%) while breathing room air. Oxygen can be administered through a nasal or nasopharyngeal catheter or an inexpensive hood or by housing the patient in a temperature-controlled oxygen cage (see Chapter 137). Patients receiving oxygen via a nasal catheter or a hood should receive humidified oxygen at rates of 50 to 100 ml/kg/minute. Higher flow rates are necessary for patients housed in an oxygen cage. In general, patients with PaO_2 of 60 mm Hg or less

while receiving supplemental oxygen are candidates for mechanical ventilation (see Chapter 138).

Physical therapy can be especially important in facilitating clearance of secretions from the lower airways, particularly in recumbent patients. Coupage, the administration of rapidly repeated, forceful chest compressions, is a means of stimulating cough and promoting clearance of airway secretions and should be performed several times daily. There is no role for the use of antitussive drugs in patients with bacterial pneumonia. Patients that are recumbent risk developing consolidating pneumonia and atelectasis. It is important that the recumbent patient be turned every 1 to 2 hours throughout the day. Upright positioning and encouraging the patient to take short walks can be important.

TREATMENT FAILURE

The clinician needs to follow the patient's response to therapy carefully, particularly in cases treated with empiric antibiotic therapy. Continued deterioration in the face of treatment, which can occur within 24 hours, may culminate in death if not managed appropriately and in a timely manner. Given the diverse causes of pneumonia, the clinician must be particularly aggressive in determining whether or not an underlying disorder, or principal primary cause, is contributing to the inability of an individual patient to respond. Pulmonary neoplasia, recurring regurgitation with aspiration, ciliary dyskinesia, laryngeal paralysis, and infection with an atypical microorganism are potential considerations.

Failure to respond may also be a consequence simply of having selected an antibiotic that is ineffective against the causative bacterium. For example, infections with *B. bronchiseptica* or *Mycoplasma* spp. may not respond to some broad-spectrum antibiotics but may demonstrate a positive response to doxycycline. In cases failing to respond, establishing the nature of the infection through isolation and susceptibility testing becomes imperative. Patients that clearly fail to respond to initial treatment and do not have an underlying disorder should receive aggressive antimicrobial therapy, preferably administered parenterally until such time that the causative organism can be confirmed.

Noncardiogenic Pulmonary Edema

KENNETH J. DROBATZ, *Philadelphia, Pennsylvania*

H. MARK SAUNDERS, *Shelburne, Vermont*

Pulmonary edema is defined as an abnormal accumulation of fluid in the extravascular spaces of the lung. It is a dynamic clinical syndrome attributable to a variety of disease processes. Noncardiogenic pulmonary edema is caused by an increase in vascular endothelial permeability rather than from increased vascular hydrostatic pressure as seen in cardiogenic pulmonary edema.

Increased permeability in noncardiogenic pulmonary edema (NPE) originates from an injury to the pulmonary microvascular endothelium that separates the intravascular compartment from the pulmonary interstitium and alveoli. In contrast to hydrostatic or cardiogenic pulmonary edema, the increase in permeability results in extravascular fluid that is relatively high in protein and leads to an increase in extravascular lung water content at lower pulmonary hydrostatic pressures.

NPE can reflect the pulmonary response to a primary pulmonary injury only or to disease processes elsewhere in the patient. The common causes of primary pulmonary epithelial injury include aspiration of gastric contents, near drowning, inhalation of smoke or toxic gases, blunt trauma, or high inspired oxygen concentrations for prolonged periods. Extrapulmonary-mediated insults include systemic sepsis, neurogenic pulmonary edema, pancreatitis, uremia, systemic inflammatory response syndrome, and pulmonary embolism.

DIAGNOSIS

NPE is a reasonable differential diagnosis in any critical animal that is showing signs of respiratory distress. The clinical difficulty is to distinguish this form of pulmonary edema from that of cardiac origin; treatment varies depending on the etiology. The form of pulmonary edema is not always clear, and on rare occasions both cardiogenic and NPE may be present simultaneously. In the absence of direct measurement of pulmonary artery wedge pressures, clinical acumen and experience are essential to reaching a diagnosis, beginning with a thorough history and physical examination.

The history may provide information for a diagnosis, such as exposure to electrical cords, head or chest trauma, upper airway obstruction, exposure to toxins, or inhalation of smoke. A thorough physical examination should include all organ systems to detect the presence of systemic disease. Evaluation of the pulmonary and cardiovascular systems is essential for determining the presence

and severity of pulmonary edema. There are no pathognomonic physical signs for NPE. Particular attention should be given to the presence of cardiac abnormalities such as a cardiac murmur, gallop, or arrhythmia; poor pulse quality; jugular pulses; and prolonged capillary refill time. Secondary cardiac signs may occur from NPE or mediators from systemic inflammation, confusing the physical determination of cardiogenic versus NPE. Unfortunately, when animals present with severe respiratory distress, restraint can be stressful and detrimental to the patient. Therefore a thorough physical examination may not be possible until the animal has been stabilized.

Thoracic radiographs should be obtained once the patient is stabilized. Review of the thoracic radiographs helps to differentiate cardiogenic from NPE, determine the extent and severity of pulmonary edema, reveal additional pulmonary or pleural space abnormalities, and serve as a reference point after instituting treatment. Interstitial or mixed interstitial-alveolar infiltrates in the more compliant perihilar region in dogs are more compatible with cardiogenic pulmonary edema and should be accompanied by left-sided cardiomegaly and pulmonary venous distention. Cardiogenic pulmonary edema in cats is rarely isolated to the perihilar region and is typically characterized by a diffuse distribution of multifocal interstitial or mixed interstitial-alveolar infiltrates. Early NPE typically appears radiographically as an interstitial pulmonary edema; although, by the time animals with acute edema are radiographed, the edema may have worsened, and the pulmonary pattern progressed to a mixed interstitial-alveolar or alveolar pattern. The location of NPE in the lung is variable, depending on the underlying etiology; caudodorsal and caudodorsal/diffuse involvement predominate. Symmetric or asymmetric distribution may depend on the inciting cause of the edema. For example, more systemic, extrapulmonary-mediated insults are more likely to cause symmetric involvement, whereas primary pulmonary epithelial injury such as inhalation of toxic fluids or near drowning may cause asymmetric pulmonary edema.

Arterial blood gases are not characteristic of NPE but often reflect pulmonary dysfunction, revealing hypoxemia caused by ventilation-perfusion mismatch. The partial pressure of alveolar carbon dioxide initially is low because of hyperventilation in response to the pulmonary parenchymal disease and, if severe, hypoxemia. In the later stages compromised pulmonary compliance can interfere with the animal's ability to ventilate,

causing hypercapnia. Serum transferrin and total protein concentration have been suggested as diagnostic tests for differentiating permeability edema from cardiogenic pulmonary edema in humans (lower concentrations are more consistent with a permeability edema). This has not been evaluated in animals, but hypoproteinemia has been reported in dogs with acute respiratory distress syndrome. A complete blood count, serum chemistry profile, and urinalysis round out the initial diagnostic tests that should be performed in searching for an underlying cause of NPE. When available, echocardiography can be invaluable for identifying, or ruling out, evidence of left-sided heart disease. This study is especially helpful in cases of cardiomyopathy.

In summary, the diagnosis is not achieved by measuring one parameter. It involves assessing a combination of the history, physical abnormalities, thoracic radiographs, arterial blood gas measurements, and clinical laboratory test results. The measurement of pulmonary capillary wedge pressure (PCWP) is sometimes necessary for ruling out an increased hydrostatic cause of the pulmonary edema. However, such measurements are not yet routine in veterinary critical care.

INITIAL APPROACH AND MANAGEMENT

Ideally the identification and elimination of the inciting cause of NPE might result in dissipation of the pulmonary edema. Corticosteroids and blockers of the cyclooxygenase and leukotriene pathways have not been proven to definitely and consistently resolve the pulmonary inflammatory process occurring in most patients with NPE. A variety of other therapies have been attempted but also have not shown consistent promise; some are even detrimental. These frustrating results may be a reflection of how permeability edema varies over time within an animal, how it differs among animals, and how it sometimes varies even within the lungs of an affected animal. In lieu of specific therapies for the underlying disease process or resolution of the pulmonary endothelial inflammation, a nonspecific approach involving supporting the respiratory and cardiovascular systems is the current mainstay of treatment.

An animal that is presented in severe respiratory distress is a challenge; the restraint required for diagnosis and treatment could result in death. When possible, an intravenous catheter should be placed to allow rapid vascular access. Immediate oxygen therapy by oxygen cage, nasal oxygen, or intubation and ventilation can be life-saving during the initial assessment and stabilization (see Chapter 137). The veterinarian may immediately be faced with the decision whether to sedate and/or anesthetize the patient for intubation and ventilation support (see Chapter 138). The acute, critical nature of some cases of NPE is such that ventilation may be required for obtaining initial stabilization.

Positive-pressure ventilation (PPV) opens collapsed alveoli and small airways to increase the number of ventilated alveoli, thereby decreasing intrapulmonary shunting. NPE decreases lung compliance so that greater than normal inspiratory pressures (20 cm H₂O) are usually necessary for generating adequate tidal volumes of 10 to 20 ml/kg.

Inspired oxygen concentrations of more than 50% for 12 hours or longer might cause oxygen toxicity. Maintaining the animal on the lowest oxygen concentration possible to correct hypoxemia minimizes the chances of toxicity. Positive end-expiratory pressure (PEEP) is often used as an adjunct to mechanical ventilation with the goal of providing an adequate partial pressure of oxygen in alveoli at a low mean airway pressure and low inspired oxygen concentration. It can also be used in spontaneously breathing patients. PEEP increases functional residual capacity, prevents alveolar and small airway collapse between breaths, and allows more alveoli to participate in gas exchange. The adverse effects of PEEP and PPV are similar. Both of these treatments can cause a decrease in venous return and cardiac output. In addition, barotrauma and pneumothorax are not unusual sequelae in patients with NPE receiving high PEEP and end-inspiratory pressures from PPV. More recently low lung-stretch ventilation techniques (permissive hypercapnia) have been shown to reduce ventilator-induced lung injury in people. It has also been postulated that the hypercapnia itself may attenuate lung and systemic organ injury.

Oxygen delivery to the tissues can be maintained despite hypoxemia if cardiac output is increased. Cardiac function in animals with NPE can be adversely affected by hypovolemia, depressed myocardial contractility, and vasoconstriction. Low blood volume results in poor venous return to the heart, poor cardiac output, and systemic hypotension. Fluid administration to increase blood volume, cardiac preload, and subsequent cardiac output helps improve tissue perfusion. However, the major concern with fluid infusion is the very real potential that *fluid therapy may increase pulmonary edema* in patients with NPE. The choice of crystalloids versus colloids is a continuing controversy. The decrease in intravascular oncotic pressure and the increase in hydrostatic pressure associated with crystalloid infusion promote pulmonary edema in patients with increased pulmonary capillary permeability. On the other hand, colloid solutions do not necessarily decrease the incidence of pulmonary edema and may be hazardous in the setting of altered pulmonary capillary permeability. The loss of colloid particles into the pulmonary interstitium would result in increased interstitial oncotic pressure and a subsequent increase in extravascular lung water. The relative permeability of the pulmonary microvasculature during disease states cannot be predicted clinically. A test infusion of a colloidal solution and monitoring the intravascular colloid osmotic pressure might provide insight into the ability of the vasculature to retain the infused colloids. No improvement, or a rapid decrease in colloid osmotic pressure, suggests that the colloid is rapidly lost from the vasculature, and its use in the patient should be restricted. Thus available data are contradictory on the comparative benefits of crystalloids and colloids with regard to pulmonary function in patients with NPE. Until more information is available, the choice of fluid therapy must be made on a patient-by-patient basis and according to the clinician's preference and experience.

Blood transfusions can optimize oxygen delivery. We recommend transfusion of whole blood or packed red blood cells to animals with NPE up to a packed cell volume

of 30%. As the packed cell volume rises above 30%, the associated increase in blood viscosity and its deleterious effects on blood flow tend to negate any increases in oxygen delivery caused by the higher hemoglobin concentration.

High pulmonary microvascular hydrostatic pressure enhances fluid transudation across the vessel wall and worsens pulmonary edema. The goal is to achieve a normal pulmonary hydrostatic pressure (measured by PCWP) and to maintain tissue oxygen delivery. In the absence of PCWP measurement, measurement of central venous pressure (CVP) might be useful, keeping in mind that the CVP might not reflect PCWP in patients with pulmonary or cardiac disease. CVP and PCWP measure hydrostatic pressure and therefore may be poor criteria for predicting the development or monitoring the progression of pulmonary edema in animals with a capillary permeability defect.

Diuretics and vasodilators may be used to decrease pulmonary microvascular hydrostatic pressure. Our first choice for a diuretic is furosemide. In dogs the initial dose is a 2-mg/kg bolus intravenously or intramuscularly if intravenous access is not available. This dose is repeated every 6 to 8 hours. Continuous intravenous infusion of furosemide has been demonstrated to have an improved diuretic response in critically ill patients. We use a dosage of 0.1 mg/kg/hour of furosemide as a continuous infusion. If PCWP is very high, a systemic vasodilator such as nitroprusside (1 to 10 mcg/kg/minute constant-rate infusion) can rapidly lower PCWP. Systemic hypotension and decreased tissue oxygen delivery must be avoided if diuretics or vasodilators are being used as part of therapy. Monitoring blood pressure is warranted, particularly when one uses vasodilators. Systemic hypotension (mean arterial pressure <80 mm Hg) in an animal with adequate blood volume indicates the need for a positive inotrope. Both dopamine (5 to 10 mcg/kg/minute) and dobutamine (5 to 20 mcg/kg/minute) can be used to increase myocardial contractility and improve cardiac output and may prevent the volume overloading associated with excessive fluid therapy. More recently β -adrenergic stimulation has been shown to enhance alveolar edema clearance in some animal models of lung injury. More studies are necessary to determine if these drugs are useful in our clinical patients.

MONITORING THE EFFECTIVENESS OF THERAPY

Frequent assessment of mucous membrane color, capillary refill time, heart rate, pulse quality, thoracic auscultation, and respiratory rate and effort provides vital subjective information on the response to therapy. Serial pulse oximetry and arterial blood gas measurement provide more objective information about pulmonary function.

Total thoracic compliance can be measured in intubated patients. A decrease in this measure often precedes the clinical signs of pulmonary edema from fluid overload in humans. The resolution of NPE on thoracic radiographs is characterized by a shift from an alveolar to a mixed alveolar-interstitial and finally an interstitial pattern. Improvement of the radiographic pulmonary pattern lags behind the animal's clinical improvement.

Patients with NPE often have multiple organ problems and therefore warrant intensive monitoring of extra-pulmonary organs such as the cardiovascular, central nervous, and renal systems. Measurement of blood pressure; cardiac rhythm; and more extensive cardiovascular parameters such as CVP, PCWP, cardiac output, systemic vascular resistance, oxygen delivery, and oxygen consumption provides more detailed information regarding the patient's cardiovascular status. Urine output, serial urinalyses, and serum creatinine and blood urea nitrogen provide assessment of renal function. In patients with systemic inflammation or sepsis, coagulation parameters should be serially evaluated for disseminated intravascular coagulation. The degree of monitoring should reflect the severity of the disease process, with the more severely affected patients requiring the most intensive monitoring.

CHAPTER 151

Respiratory Parasites

ROBERT G. SHERDING, *Columbus, Ohio*

Various parasites, including nematodes, trematodes, protozoa, and arthropods, have a predilection for invading the nasal cavity, airways, lung parenchyma, or pulmonary arteries of dogs and cats. This chapter focuses on primary parasites of the respiratory system that live in the nasal cavity, airways, or lung tissue. Parasites that transiently migrate through the lung during development such as *Toxocara canis* and *Ancylostoma caninum* are not discussed here. Systemic parasitic infections that occasionally cause pulmonary involvement such as the protozoan *Toxoplasma gondii* also are not included. In addition, parasites that live primarily in the heart or pulmonary arteries (*Dirofilaria immitis*; *Angiostrongylus vasorum*) are beyond the scope of this chapter, although these are important causes of secondary cardiopulmonary disease.

NASAL PARASITES

Nasal parasites of clinical significance include worms, mites, and *Cuterebra* fly larvae. These cause nonspecific signs of chronic rhinitis that are difficult to distinguish from more common causes of nasal disease.

Eucoleus boehmi

Eucoleus boehmi is a small (1.5 to 4 cm in length) trichinelloid nematode that parasitizes the epithelial lining of the nasal mucosa, turbinates, and sinuses of dogs. Ova are passed into the environment with nasal discharges or with the feces when nasal secretions are swallowed. The life cycle is not well understood but may be direct or involve earthworms as transport hosts. Infection may spread among dogs kennelled together.

Clinical Signs and Diagnosis

Eucoleus infection may be clinically inapparent or it may cause signs of chronic rhinitis, including sneezing, mucopurulent or blood-tinged nasal discharge, nasal congestion, and reverse sneezing. The diagnosis is confirmed by the microscopic identification of characteristic double-operculated (bipolar) eggs in nasal flushes or on routine fecal flotation examination. Egg excretion may be cyclic and easily overlooked. *E. boehmi* ova are easily misidentified as ova of *Capillaria aerophila* (see section on *C. aerophila* later in the chapter) because of similarity in appearance; however, *E. boehmi* ova are slightly smaller and have distinctive, readily visible spaces between the egg shells and embryonated contents. The adult *E. boehmi* nematodes occasionally may be identified in nasal mucosal biopsies.

Treatment

Treatment is either an extended course of fenbendazole (Panacur, Intervet; 50mg/kg q24h orally [PO]) for 14 days; or ivermectin (Ivomec, Merial Animal Health; 400mcg/kg subcutaneously [SC] or PO) repeated at 2-week intervals for a total of two or three doses. Ivermectin should not be administered to collies, shelties, and other herding breeds without first determining safety with an MDR1 genotype test (available at www.vetmed.wsu.edu/vcpl). Relapses can occur after initial treatment, necessitating additional courses of therapy.

Mammomonogamus ierei

This small nematode, ranging in length from 6 to 20 mm, is widespread in cats in Puerto Rico and other islands of the Caribbean, where it is found attached to the mucosal lining of the nasal cavity and nasopharynx, causing mild chronic inflammation. Clinical signs generally are minimal. The life cycle is unknown. The diagnosis is confirmed by fecal flotation to identify the typical large embryonated ova, which appear very similar to hookworm eggs. Presumably ova may also be detected in rhinoscopic cytologies or nasal flushes. Treatment of *Mammomonogamus* in cats has not been well documented, but fenbendazole (dosed as for *Eucoleus*) is suggested.

Pneumonyssoides caninum

Pneumonyssoides caninum is a small mite (1 mm in length) found worldwide infecting the nasal cavity and sinuses of dogs. The parasite is endemic in Scandinavia with over 20% of dogs infected in some regions. Nasal mite transmission is probably through direct contact with infected animals, and infection can spread between dogs confined together in the same household or kennel.

Clinical Signs and Diagnosis

Nasal mites cause nonspecific clinical signs of rhinitis and nasal irritation such as sneezing, reverse sneezing, seromucoid nasal discharge, and impaired scenting ability (hyposmia). Facial pruritus also has been reported. The diagnosis is confirmed by direct visualization of yellow-white mites, 1 to 1.5 mm in length, at the external nares or in the nasal passages by rhinoscopy or by identification of mites in nasal discharge (swabs or flushes). In some cases the mites can evade detection by locating in the frontal sinuses and caudal choanae.

Treatment

Nasal mites can be treated effectively with selamectin (Revolution, Pfizer; 6 to 12mg/kg, applied topically as a

“spot-on” to the skin over the shoulders) at 2-week intervals for a total of three doses or milbemycin oxime (Interceptor, Novartis; 0.5 to 1 mg/kg PO) at 1- to 2-week intervals for a total of three doses. Ivermectin, dosed as for *Eucoleus*, is an effective alternative, but it has a greater risk of adverse side effects. Clinical signs usually resolve rapidly with treatment. In dogs confined together effective control requires treating all animals in the household or kennel.

Cuterebra

Cuterebra spp. larvae are the larval forms (bots) of numerous species of arthropod flies that infect mostly rabbits and rodents. *Cuterebra* occasionally can infect outdoor dogs and cats in spring and summer, especially migrating in the subcutis of the face, head, and neck region. Rarely *Cuterebra* can cause respiratory disease when they migrate in the nasopharynx, causing sneezing and unilateral bloody nasal discharge, or in the wall of the cervical trachea, causing clinical signs of cough and dyspnea. The diagnosis is made by direct endoscopic visualization of the *Cuterebra* larvae embedded in the nasopharyngeal or upper airway mucosa. Airway *Cuterebra* can be treated by endoscopic extraction or by administering a single dose of ivermectin (200 to 400 mcg/kg SC; see precautions under the section on *Eucoleus*). The use of prednisone (1 mg/kg q12h PO) for 2 weeks may reduce the local inflammatory reaction to the parasite.

BRONCHOPULMONARY PARASITES

Most bronchopulmonary parasite infections are caused by metastrongyloid nematodes such as *Oslerus* (*Filaroides*) *osleri*, *Filaroides* *hirthi*, *Andersonstrongylus* (*Filaroides*) *milksi*, and *Crenosoma vulpis* in dogs and *Aelurostrongylus abstrusus* in cats. Both dogs and cats can also be infected with the trichurid lungworm, *C. aerophila* (also known as *Eucoleus aerophilus*), and the trematode lung fluke *Paragonimus kellicotti*.

Lungworm and lung fluke infections are relatively uncommon; young animals are most susceptible. Many infections are inapparent or subclinical; however, when clinical signs occur, chronic persistent cough is typical. Severe infections can cause dyspnea or be complicated by secondary bacterial bronchopneumonia. Abnormal bronchopulmonary infiltration patterns are often found on routine thoracic radiography in animals that manifest overt clinical signs. An increase in circulating eosinophils is sometimes seen on a complete blood count (CBC), but this is not consistent. Other routine laboratory evaluations are usually unremarkable. Definitive diagnosis requires identification of parasite ova or larvae in the feces or in respiratory cytology specimens.

Oslerus* (*Filaroides*) *osleri

O. osleri are metastrongyloid nematodes that live in granulomatous nodules located on the mucosal surface of the distal trachea, tracheal bifurcation, and first-division bronchi of dogs, especially puppies and young dogs less than 1 year of age. Wild canid species such as the North American coyote and Australian dingo have a high

prevalence of *O. osleri* infection and may serve as natural reservoirs of infection.

O. osleri has a direct life cycle that does not require an intermediate host; thus larvae that are coughed up, swallowed, and passed in the feces can be transmitted directly to another animal. In addition, larvae that are expelled from the trachea with respiratory secretions can be transmitted through saliva from dam to puppy during grooming behavior and regurgitative feeding. The prepatent period ranges from 10 to 18 weeks.

Clinical Signs

The primary clinical sign of *O. osleri* infection is chronic cough. A progressively enlarging granulomatous mucosal nodule or a series of confluent nodules may obstruct tracheobronchial airflow and cause exercise intolerance, dyspnea, or even death. Spontaneous pneumothorax has been reported.

Diagnosis

The distinctive tracheobronchial nodular lesions caused by *O. osleri* (Fig. 151-1) occasionally can be detected radiographically as large, space-occupying mucosal masses protruding into the lumen near the bifurcation (Fig. 151-2). These granulomatous mucosal nodules are most reliably identified by bronchoscopic visualization. The definitive diagnosis is based on finding mucosal nodules accompanied by thin-walled larvated ova (80 µm) and larvae (230 µm with kinked tail) in airway washings or bronchoscopic biopsies. Biopsies of parasitic nodules often reveal numerous *O. osleri* larvae embedded in granulomatous inflammatory tissue (Fig. 151-3).

Feces can also be examined for larvae, but this is less reliable than examination of airway specimens. For detection of *O. osleri* larvae in feces, zinc sulfate centrifugation-flotation is preferred over the Baermann technique; however,

Fig. 151-1 Tracheoscopic image of the distal trachea from a dog with *O. osleri* infection. Three mucosal masses are evident. Mature parasites can be found within or adjacent to these nodules.

Fig. 151-2 Lateral radiograph from another dog with *O. osleri* infection. Notice that the mucosal nodules and inflammatory reaction have reduced the tracheal luminal diameter (arrows).

a negative fecal examination by either method is inconclusive, detecting less than one third of active infections. This may be attributable to the presence of few larvae and an intermittent pattern of larval shedding.

Treatment

The preferred treatment for *O. osleri* infection is either an extended course of fenbendazole (50mg/kg q24h PO) for 14 to 21 days; or ivermectin (400mcg/kg SC or PO) repeated at 2-week intervals for a total of three doses. Ivermectin should not be administered to collies, shelties, and other herding breeds without first determining safety with an MDR1 genotype test (available at www.vetmed.wsu.edu/vcpl). Additional doses of fenbendazole or ivermectin may be required to achieve remission in some dogs. Treatment has also been successful with albendazole, oxfendazole, thiabendazole, and levamisole. Albendazole has been associated with serious bone marrow toxicity and should be avoided or used cautiously. In rare cases severe airway obstruction may necessitate surgical or bronchoscopic removal or debulking of obstructing parasitic nodules.

Filaroides hirthi

F. hirthi are small metastrongyloid nematodes that live deep in the lung parenchyma (alveoli and terminal airways) of dogs, causing diffuse multifocal interstitial pneumonitis that may be eosinophilic, mononuclear, or granulomatous.

F. hirthi has a direct life cycle with a prepatent period of 32 to 35 days. First-stage larvae that are coughed up, swallowed, and passed in the feces are immediately infective and can cause direct feco-oral transmission through coprophagia. This mode of transmission has been shown to occur rapidly when infected and uninfected puppies are kenneled together. In endemically infected breeding colonies, dam-to-puppy transmission is common and can result in patent infections in puppies less than 3 months

Fig. 151-3 Biopsy sample of a mucosal nodule demonstrating a portion of a female parasite carrying numerous larvae.

of age. Because first-stage larvae are infective immediately, autoinfection can lead to massive overwhelming hyperinfections, with severe clinical disease and sometimes death in severely stressed or immunocompromised dogs.

Clinical Signs

F. hirthi usually causes subclinical interstitial pneumonia, but occasionally infected dogs are presented with acute or chronic progressive signs of cough and dyspnea. Fatalities have been reported in severe infections, especially in immunocompromised or corticosteroid-treated dogs and toy breed dogs.

F. hirthi has been found to be a prevalent endemic problem in breeding colonies of beagles and other research dogs, with infection rates approaching 100% in some colonies. Dogs from such colonies generally show minimal clinical signs; however, the parasite produces significant inflammatory lung lesions that can impair their usefulness in research.

Diagnosis

Routine thoracic radiography in infected dogs with clinical signs usually reveals diffuse bronchointerstitial infiltrates, with less frequent alveolar infiltrates. These changes may persist for several weeks. A peripheral eosinophilia may be seen in some dogs. The definitive diagnosis is based on finding larvated ova or first-stage larvae in airway or bronchoalveolar cytology specimens (e.g., aspirates or washings) or in the feces. The most reliable method for examining feces for *F. hirthi* larvae is with zinc sulfate (specific gravity 1.18) centrifugation-flotation, which is much more efficient for concentrating *F. hirthi* larvae than the Baermann procedure.

Treatment

F. hirthi can be treated with fenbendazole (50mg/kg q24h PO) for 14 to 21 days or ivermectin (400mcg/kg SC or PO) repeated at 2-week intervals for a total of three doses. Ivermectin should not be administered to collies, shelties, and other herding breeds without first determining safety with an MDR1 genotype test (available at www.vetmed.wsu.edu/vcpl). Albendazole (Valbazen; 25 to 50mg/kg q12h PO) for 5 days and repeated in 2 weeks is

also effective but has been associated with serious bone marrow toxicity and should be avoided or used cautiously. Dead and dying worms can elicit a multifocal granulomatous inflammatory response; thus clinical signs and radiographic changes may worsen initially after treatment. If severe, these changes can be controlled with prednisolone (1 to 2 mg/kg q12 to 24h PO) for 2 to 3 weeks and then tapered.

Control of *F. hirshi* infection in kennels and breeding colonies can be challenging because of high infection rates approaching 100% and direct transmission from dam to puppies. Isolation procedures and kennel sanitation measures are helpful adjuncts to medical management. Because they have longer residual activity than ivermectin, it has been suggested that selamectin and moxidectin should be investigated for efficacy in controlling *F. hirshi* reinfection in dog colonies.

Andersonstrongylus (Filaroides) milksi

A. milksi, also known as *F. milksi*, is a rare metastrongyloid nematode of dogs that has many similarities to *F. hirshi*. There is considerable confusion and some disagreement regarding the taxonomic classification of this parasite. Some of the early reports of this parasite in dogs are now considered to be misidentified *F. hirshi* infections. As in *F. hirshi*, this lungworm has a direct life cycle. Clinical findings, diagnosis, and treatment of *A. milksi* are thought to be similar to those of *F. hirshi* (see preceding section).

Aelurostrongylus abstrusus

A. abstrusus, the feline lungworm, is a metastrongyloid nematode that infects cats worldwide, especially feral, stray, and outdoor cats that eat prey. The adult *Aelurostrongylus* nematodes live in the terminal bronchioles and alveolar ducts, causing bronchiolitis, interstitial and alveolar pneumonia, and muscular thickening of the pulmonary arteries. The adult female worms are 9 to 10 mm in length, and the males are 4 to 6 mm. Eggs produced by the adult nematodes develop within the lung of the cat into first-stage larvae that are coughed up, swallowed, and passed in the feces. The indirect life cycle requires a molluscan intermediate host such as a terrestrial snail or slug. Cats can be infected either by ingesting infected snails and slugs or by eating transport and storage hosts such as rodents and birds that may harbor infectious larvae after feeding on infected snails and slugs. Infected cats begin excreting larvae 1 month after infection and continue for 6 to 9 months.

Bronchostrongylus subcrenatus and *Troglostrongylus subcrenatus* are metastrongyloid nematodes that are related to *A. abstrusus* and cause a similar lungworm disease in domestic cats and exotic felids in Africa.

Clinical Signs

Most *Aelurostrongylus* infections are clinically inapparent; however, severe infections can cause chronic cough, dyspnea, and debilitation. Pleural effusion, which may be eosinophilic, occurs rarely. Studies in experimentally infected kittens indicate that the severity of pulmonary disease and clinical signs are related to the infective dose

of larvae, with heavy infections producing severe diffuse pulmonary inflammation and progressive clinical signs of cough, dyspnea, inappetence, debilitation, and sometimes death. In less severe infections the clinical signs and pulmonary lesions are self-limiting within 6 to 9 months. Thickening of the pulmonary arteries may persist for 2 years or more after recovery, but this does not appear to have adverse clinical consequences.

Diagnosis

A. abstrusus infection can mimic feline “asthma” and should be suspected in cats with bronchopulmonary disease that have a history of hunting birds and rodents. Radiographic findings of diffuse bronchointerstitial and patchy alveolar pulmonary infiltrates are typical and correspond to a dense inflammatory infiltration of lymphocytes, macrophages, and eosinophils around multifocal collections of eggs and larvae. An alveolar infiltrative radiographic pattern is most pronounced at 1 to 5 months after infection, followed by a bronchial or miliary interstitial nodular pattern that persists for up to 10 months after infection. Eosinophilia is found on CBC in some cats with aelurostrongylosis.

Confirmation of *Aelurostrongylus* infection is based on identification of first-stage larvae in airway or bronchoalveolar lavage cytology specimens or in the feces using either a Baermann fecal examination or zinc sulfate centrifugation-flotation. Larvae are 0.4 mm in length with a notched tail and configured in a coil or J shape. Although the Baermann fecal examination is considered a relatively sensitive clinical diagnostic test for *Aelurostrongylus* infection, larvae are shed intermittently in small numbers in feces; thus evaluation of respiratory cytology specimens for larvae can sometimes identify infections that are not detected by fecal examination.

Treatment

Mild *Aelurostrongylus* infections are generally self-limiting without treatment; however, cats with significant clinical pulmonary disease should be treated. The safest and most consistently effective treatment is fenbendazole (50 mg/kg q24h PO) for an extended duration of 14 to 21 days. Alternatives that are not as reliable include selamectin (6 to 12 mg/kg, as a topical “spot-on” application to the interscapular skin) at 2-week intervals for a total of three doses; or ivermectin (400 mcg/kg SC or PO) repeated at 1- to 2-week intervals for a total of two or three doses. Adjunctive therapy can include an antiinflammatory dosage of prednisolone (2 to 3 mg/kg q12 to 24h PO) for 2 weeks and then tapered; and a bronchodilator such as terbutaline (0.625 to 1.25 mg total dosage q8-12h PO) or inhaled albuterol (Ventolin; 90 mcg aerosol, 10 breaths by metered-dose inhaler q12h or as needed).

Crenosoma vulpis

C. vulpis is a metastrongyloid nematode that occasionally causes chronic bronchopulmonary disease and productive cough in dogs. Wild canids (wolves, foxes) and raccoons in North America and Europe serve as important natural reservoirs for this lungworm. In North America infection is widespread in the wild fox population and

is endemic in red foxes in the northeastern United States and Atlantic provinces of Canada, with a prevalence of over 50% in red foxes of Nova Scotia, New Brunswick, and Prince Edward Island. In these regions *C. vulpis* can be an important cause of respiratory disease in dogs residing in rural or urbanized areas populated with foxes.

C. vulpis has an indirect life cycle that requires terrestrial snails and slugs as intermediate hosts, similar to *A. abstrusus* in cats. Dogs become infected by ingesting either infected snails and slugs or small prey that act as transport hosts after they feed on snails and slugs. The adult nematodes (females 12 to 16 mm in length and males 4 to 8 mm) live in the bronchi and bronchioles where they cause chronic bronchitis and bronchiolitis. After 17 to 21 days of infection the adult lungworms produce larvated eggs that develop into first-stage larvae that are coughed up, swallowed, and passed in the feces.

Clinical Signs

The predominant clinical sign of *C. vulpis* infection is chronic productive cough. Systemic signs such as fever, inappetence, or weight loss are usually absent.

Diagnosis

Thoracic radiography usually reveals a diffuse bronchial or bronchointerstitial pattern that may be indistinguishable from other causes of chronic bronchitis. Alveolar infiltrates are found less commonly. Hematologic findings can include eosinophilia, basophilia, or monocytosis.

Bronchoscopic findings vary from mild bronchial erythema to severe bronchitis with mucus accumulation and hyperplastic mucosal nodules. Bronchial hemorrhage is seen infrequently. Adult worms are visualized rarely. Tracheobronchial or bronchoalveolar lavage cytology specimens usually show increased mucus, high cellularity, and predominantly eosinophilic inflammation. First-stage larvae are identified cytologically in only 50% to 75% of cases.

Definitive diagnosis of *C. vulpis* infection depends on identification of first-stage larvae in airway cytology specimens or in feces, preferably using a Baermann procedure, which is reportedly a more reliable detection method for *C. vulpis* larvae than either zinc sulfate centrifugation-flotation of feces or bronchoalveolar lavage. *C. vulpis* larvae are approximately 300 μ m in length with a blunt anterior end and a smooth tapering tail without notching or kinks.

Treatment

C. vulpis responds rapidly to treatment with fenbendazole (50 mg/kg q24h PO) for 3 to 7 days or a single dose of milbemycin oxime (0.5 mg/kg PO). Clinical signs and radiographic abnormalities generally improve within 1 week, and fecal larvae are absent within 2 to 4 weeks. Other successful treatments for *Crenosoma* have included febantel, levamisole, diethylcarbamazine, and ivermectin.

Capillaria aerophila

C. aerophila, also known as *E. aerophilus*, is a trichuroid nematode parasite found worldwide that infects the tracheobronchial mucosa of dogs, cats, and foxes. A prevalence rate

of 1% to 5% is reported in various surveys of dogs and cats. The adult female worms are 20 to 38 mm in length, and the males are 12 to 25 mm. Adults begin producing ova 3 to 5 weeks after infection. These parasites embed deeply in the mucosa of the trachea and large bronchi, forming white, coiled masses surrounded by collections of ova. This results in chronic bronchitis. The direct life cycle involves ingestion of eggs from an infected host that are passed in the feces after being coughed up and swallowed. Earthworms may serve as transport hosts. Excreted eggs embryonate and become infective in about 40 days, remaining viable in the soil for extended periods of up to a year.

Clinical Signs

C. aerophila usually causes a clinically inapparent infection; however, occasionally it can cause chronic bronchitis with persistent cough. In severe cases dyspnea, loss of weight, poor body condition, or complicating bacterial bronchopneumonia may occur, especially in young animals.

Diagnosis

In animals with clinical signs thoracic radiographs may reveal a mixed pattern of diffuse peribronchial, interstitial, and alveolar infiltrates. Some dogs develop a marked peripheral eosinophilia. Airway cytology specimens may show increased mucus, eosinophilic inflammation, and the presence of *Capillaria* ova.

The diagnosis is based on identification of double-operculated yellow-brown ova in fecal flotation or airway cytology specimens. *Capillaria* ova must be differentiated from the similar-appearing ova of the intestinal whipworm (*Trichuris vulpis*) and the nasal nematode *E. boehmi* (see section on Nasal Parasites). *Capillaria* ova are smaller (<70 μ m) than *Trichuris* ova, and they have asymmetric bipolar plugs that produce a distinctive lopsided appearance.

Treatment

The suggested treatment for *Capillaria* is fenbendazole (50 mg/kg q24h PO) for an extended duration of 14 to 21 days. It is not clear whether fenbendazole actually kills the adult nematodes or merely disrupts egg shedding by sterilizing the female worms. Ivermectin (200 to 400 mcg/kg SC or PO) repeated at 2-week intervals for a total of three doses can also be used to treat capillariasis; however, ivermectin should not be administered to collies, shelties, and other herding breeds without first determining safety with an MDR1 genotype test (available at www.vetmed.wsu.edu/vcpl). Levamisole has also been effective. A combination of febantel and praziquantel was not effective for treating *Capillaria* in cats.

Paragonimus kellicotti

P. kellicotti is a trematode lung fluke that infects wild carnivores and occasionally dogs and cats, especially in the Great Lakes and Gulf state regions of the United States. The lung fluke requires two intermediate hosts—the aquatic snail and the crayfish. Dogs and cats become infected by ingesting infected crayfish or by eating another animal that has recently ingested crayfish. Within 4 to 5 weeks

after infection, the flukes are well established in radiographically visible pulmonary cysts, and they begin producing ova that appear in the feces. These cysts are most prevalent in the caudal lung lobes, especially on the right side. The adult flukes live in pairs within fibrous subpleural cysts that communicate directly with the bronchial system. This allows eggs to be readily expelled into the airway, where they are coughed up and then swallowed and passed in the feces to complete the life cycle.

Clinical Signs

The typical clinical signs of paragonimiasis are chronic cough, exercise intolerance, and weight loss. Hemoptysis is sometimes observed. In some cases sudden or recurrent episodes of dyspnea can be caused by spontaneous pneumothorax from cyst rupture. Clinically inapparent infections also occur.

Diagnosis

In dogs the diagnosis of *Paragonimus* infection should be suspected when radiographs reveal multiloculated thin-walled pulmonary cysts and large coalescing cavitations. Radiographic findings in cats are thick-walled cysts and large ill-defined nodular densities (granulomas). Some dogs and cats have radiographic evidence of spontaneous pneumothorax. Nonspecific peribronchial and linear interstitial infiltrates are common. Routine laboratory evaluations are unremarkable except for mild eosinophilia in some cases. Definitive diagnosis is based on identification of characteristic large yellow-brown, single-operculated ova in feces using fecal sedimentation technique or zinc sulfate centrifugation-flotation or in airway cytology specimens.

Treatment

P. kellicotti is treated effectively with either praziquantel (Droncit; 25 mg/kg q8h PO) for 3 days, or fenbendazole (50 mg/kg q24h PO) for an extended duration of

14 days. Albendazole (25 mg/kg q12h PO) for 10 days is also effective but should be avoided or used cautiously because of the potential for serious bone marrow toxicity. With successful elimination of the flukes, the radiographic lung lesions rapidly improve, and ova disappear from the feces.

Interstitial Lung Diseases

BRENDAN M. CORCORAN, *Edinburgh, Scotland*

Strictly speaking, the lung interstitium is that part of the lung that does not include the airspaces, the capillary endothelial cells, and the alveolar lining epithelium. However, in disease it would be very unusual for only these structures to be affected, and inflammatory and infiltrative diseases of the true interstitium also affect the adjacent alveolar walls. With that consideration, it is often better to refer to the interstitial lung diseases (ILDs) as the diffuse parenchymal lung diseases. However, if infiltrative processes extend to include the alveolar spaces, the disease process is more properly categorized as pneumonia.

DISEASES OF THE LUNG INTERSTITIUM

Diseases of the lung interstitium are poorly defined in the dog and cat, and only recently are veterinarians beginning to properly understand the pathologic mechanisms involved in some of them. By inference these diseases involve pathologic processes that are restricted to the interstitial structures, but in reality they tend to also involve adjacent structures, giving a more complex pathologic profile. In addition, these diseases compromise respiratory function and can secondarily initiate other types of respiratory pathology. The most readily recognized disease entities are pulmonary infiltration with eosinophilia (PIE) (also known as eosinophilic bronchopneumopathy) and idiopathic pulmonary fibrosis (IPF). Parasitism in dogs and cats can be a contributory factor to the eosinophilic airway and lung diseases. The type of parasites involved depend on geographic location but can include *Filaroides* spp. (*Oslerus osleri*, *Filaroides hirhti*), *Crenosma vulpis*, *Aelurostrongylus abstrusus*, *Capillaria aerophila*, and the heartworms *Angiostrongylus vasorum* and *Dirofilaria immitis* (see Chapter 151). In humans there is a large group of occupational and toxin- and drug-induced ILDs, but of these the only one that can be readily identified in the dog is paraquat poisoning (Box 152-1). Connective tissue and vasculitis disorders are also a significant problem in human medicine and can involve the lung; but identifying similar disease entities in the dog and cat is difficult, or it is difficult to show that such entities consistently affect the lung of dogs and cats. Several ILD conditions reported in humans are pathological descriptions, such as lymphocytic infiltrative disorders, and are unlikely to be identified in dogs and cats without more widespread availability of pathological data. Possibilities of infectious agents such as viruses and neoplastic processes (lymphoma) causing ILD exist. In addition groups of clinical conditions can involve the interstitium, such as pulmonary edema (cardiogenic and noncardiogenic) and lung parasitism, and syndrome entities such as acute respiratory distress syndrome; but

invariably these involve other parts of the lung and thus strictly speaking are not ILDs. Bacterial bronchopneumonia and the mycotic pneumonias (specific geographic locations worldwide) could also be included in this group. Interstitial lung changes detected radiographically can be the consequence of a disease process elsewhere such as metastatic mineralization with hyperadrenocorticism or even a consequence of natural aging changes (Box 152-2). Many of the ILDs reported in human medicine are extremely rare, and it is possible that they exist in dogs and cats but that as yet they have not been identified. This chapter concentrates on IPF and PIE since they are the two best known examples of ILD.

DIAGNOSIS AND DIAGNOSTICS

Considering the possible disease entities included in the ILDs and the way many disease processes can involve the interstitium as part of their spectrum of pathologic changes, it can be difficult to definitively identify a “true” interstitial disease. In effect these diseases are suspected in dogs with tachypnea or lung crackles because of radiographic changes that are best described as “interstitial” and in which there is no (or minimal) radiographic evidence of bronchial or alveolar changes. The definition of the appearance of an interstitial lung pattern is itself problematic. Furthermore, the issue of radiographic quality is a major confounding factor in identifying interstitial lung patterns. An interstitial lung pattern can be best described as nodular or reticular linear densities where there is no evidence of increased bronchial markings or alveolar changes (i.e., air bronchograms). In a practical clinical situation the interstitial pattern is often determined by the exclusion of other obvious explanations for abnormal radiographic densities.

Radiography must be used with caution in the diagnosis of ILDs; and confounding factors such as exposure settings, body conformity, obesity, and stage of respiration need to be considered. In addition, subtle interstitial lung patterns are extremely difficult to identify with an acceptable degree of certainty. The use of high-resolution computed tomography (HRCT) can greatly improve the quality of thoracic imaging and the identification of genuine interstitial lung patterns, but its use is constrained by availability and cost. For IPF typical HRCT findings include ground glass opacity, subpleural bands, parenchymal bands, subpleural and peribronchovascular interstitial thickening, and traction bronchiectasis; and these changes appear to correlate well with the severity of disease (Johnson et al., 2005).

Routine hematology and biochemistry profiles are worth undertaking in suspect ILD cases, but they rarely give significant or specific changes. The presence of a

circulation eosinophilia may be found in some cases of PIE, whereas the presence of basophilia would be very suspicious. A leukocytosis with a left shift should alert to the possibility of bacterial bronchopneumonia being present rather than an ILD.

Bronchoscopic evaluation of the respiratory system is invaluable in the investigation of the suspect ILD case, particularly in its ability to identify other disease entities that may be contributing to the respiratory problem or diseases that secondarily contribute to chronic interstitial lung changes. In PIE excess, often green-tinged secretions may be identified; whereas in IPF often little abnormality is detected apart from dynamic airway collapse. During bronchoscopy there is the opportunity to obtain airway samples and to carry out bronchoalveolar lavage. In PIE this should yield an eosinophil-rich sample (required for definitive diagnosis); but in IPF little abnormality is identified in samples, or there may be evidence of low-grade nonspecific inflammation.

Pulmonary function testing and blood gas analysis can be applied to the investigation of ILD, but the former is rarely used because it requires specialized equipment and training and there are limited normal reference values. Nevertheless the ILDs are likely to result in reduced lung compliance, and there is some unpublished evidence that this is the case with IPF. With respect to blood

gas abnormalities, these diseases are most likely to result in ventilation-perfusion mismatch, and the degree of hypoxemia is determined by the severity of the disease. However, the contribution of true diffusion impairment to the blood gas picture is unknown. The degree of venous admixture can be derived from calculation of the alveolar-arterial PO_2 gradient, and in dogs with severe IPF it is abnormally high.

Definitive diagnosis of the ILDs can only be achieved by histopathologic assessment of lung tissue samples. Sufficient lung biopsy samples are rarely obtained. Transthoracic lung biopsy is usually ineffective in obtaining diagnostic material. This is in part because of the diffuse and patchy distribution typical of these diseases. Nevertheless, in some cases of PIE eosinophil-rich samples can be obtained in this manner, but it is usually only attempted if airway samples have been negative and there is a high index of suspicion that PIE is present. Open-chest and video-assisted thoracoscopic (VAT) lung biopsy are the only techniques that allow sampling of site-specific tissue. The techniques are rarely used because of the potential morbidity and mortality problems and the lack of skills or sophisticated thoracoscopic equipment. Nevertheless, greater use of VAT by specialized referral centers will make lung biopsy more common in veterinary practice. In IPF there is some information on the histopathologic appearance of diseased tissue, which includes patchy but extensive alveolar fibrosis, epithelial cell hyperplasia, squamous

metaplasia, and varying degrees of inflammatory reaction; but the exact pathologic descriptors for IPF in the dog still need to be determined. VAT has allowed identification of cases of bronchiolitis obliterans with organizing pneumonia, lymphoplasmacytic ILD, and hypersensitivity pneumonitis in the dog and cat (Norris, Griffey, and Walsh, 2002). Pathological description of IPF in the cat is more complete, and both desquamative and usual interstitial pneumonitis (UIP) have been described (Rhind and Gunn-Moore, 2000; Williams et al., 2004). UIP is now recognized as the definitive pathological description of IPF in humans, but this pathological profile still has to be identified in the dog.

In practice ILDs are usually diagnosed on the basis of historical and clinical features supported by radiographic, bronchoscopic, and airway cytology results. For example, in IPF it is the clinical features of dyspnea with extensive pulmonary crackles in a predisposed middle- to old age-breed of (West Highland white terrier, cairn terrier) that gives the highest index of suspicion as to the diagnosis (Corcoran et al., 1999). In PIE it is the detection of large numbers of eosinophils in airway samples of a dog with respiratory signs or unexplained lung infiltrates that would support a diagnosis (Corcoran et al., 1991).

THERAPY

Therapy depends on identifying the underlying cause or the specific disease process. In some instances specific treatment modalities are used, but empiric or symptomatic therapy may be the only option. Depending on the degree of respiratory impairment and the chronicity of the clinical presentation, varying degrees of supportive care need to be considered. These can include periodic hospitalization, oxygen supplementation, nutritional care, obesity control, and planned exercise. PIE is treated with glucocorticosteroids (prednisone, 1 mg/kg q12h orally [PO], reducing to 0.25 mg/kg q48h over 2 to 3 weeks) and should result in a rapid and complete response. Subsequent recurrent or long-term maintenance therapy with oral prednisone may be required in some cases, but complete remission can occur in many cases. Concurrent treatment with a benzimidazole anthelmintic (fenbendazole, 50 mg/kg q24h PO for 7 days) is advisable in case there is parasitic involvement.

Effective medical treatment for IPF is not currently available. However, some affected dogs show a partial and transient favorable response to oral prednisolone at antiinflammatory doses (the suspicion is that such cases do not have IPF). The use of sildenafil in human patients and in dogs with IPF that also have concurrent pulmonary hypertension appears to be beneficial in some cases. The addition of bronchodilators can be beneficial in some cases but should be discontinued if there is no obvious response. The effectiveness of azathioprine and the antifibrotic agent colchicine in this disease are unknown in dogs and cats. Many other medications are being evaluated in human IPF, but the only agents that appear to have some promise are pirfenidone and hydroxyproline analogs. The possibility of these being effective in canine IPF is also unknown. The treatment of other conditions that can cause an interstitial lung pattern on radiographs such as pulmonary edema and the mycotic pneumonias is well described, and the reader should consult other chapters for exact treatment details.

Pleural Effusion

ELEANOR C. HAWKINS, *Raleigh, North Carolina*

THERESA W. FOSSUM, *College Station, Texas*

Pleural effusion is a common disorder of dogs and cats. This condition can represent a subtle sign of serious disease or a medical emergency. Causes of pleural effusion vary (Box 153-1), and determining the cause impacts both prognosis and therapy. Thoracic radiography, routine laboratory tests, thoracic/cardiac ultrasound, and cytologic and biochemical analyses of the pleural effusion are common diagnostic studies. Therapy can be medical, surgical, or both.

INITIAL MANAGEMENT OF PLEURAL EFFUSION

Respiratory distress from pleural effusion is caused by the inability of the lungs to expand; therefore immediate thoracocentesis is indicated to stabilize these animals. Thoracocentesis is also indicated for diagnostic purposes in animals with pleural effusion, and fluid for analysis should be collected *before* initiating antimicrobial therapy. The primary risk of thoracocentesis is laceration of underlying lung tissue (resulting in pneumothorax), hemothorax, or pulmonary hemorrhage in an already compromised animal. This risk is minimized by a well-restrained animal, careful technique, and appropriate catheter selection. Local anesthesia or manual restraint alone is often adequate when performing thoracocentesis, but mild sedation facilitates restraint in animals that are anxious or fractious.

Thoracocentesis is usually performed between the seventh and ninth intercostal spaces, above the costochondral junctions. Location of focal accumulation of fluid is identified radiographically or ultrasonographically. If available, ultrasonographic guidance facilitates insertion of the needle into localized pockets of fluid.

Butterfly catheters are commonly used because they are inexpensive, readily available, and convenient. Attached extension tubing prevents movement at the syringe from resulting in movement of the needle in the chest. A three-way stopcock facilitates retrieval of fluid and prevents the entrance of outside air into the thorax. The hand of the operator that holds the wings of the catheter should always rest gently on the body wall to minimize movement of the needle with respect to the body wall and to be prepared for immediate withdrawal if the surface of the lungs is felt through the needle or restraint of the animal is lost. Once the catheter has popped through the pleura, it should be laid against the body wall with the bevel facing toward the lungs. This avoids causing damage to the pulmonary parenchyma as the lungs expand with fluid removal. Specialized catheters for thoracocentesis are also available (Argyle Thoracocentesis System,

Sherwood Medical). Although more expensive, these catheter systems have safeguards to prevent damage to thoracic viscera. Alternatively over-the-needle catheters can be used (e.g., 3.25-inch or 5.25-inch 16- or 18-gauge Angiocath, Becton Dickinson); they have several advantages over butterfly catheters. Once over-the-needle catheters are in place, there is no needle in the thorax to lacerate the lung; it is even safe to reposition the animal to maximize retrieval of fluid. These catheters are also available in long lengths, which may be necessary to reach the pleural space in large-breed or obese dogs. Extension tubing and a three-way stopcock should be attached to the catheter to facilitate fluid removal. Side openings can be added to the catheter so that obstruction of a single opening is avoided. Gloves are worn, and a surgical blade is used to shave one or two side holes in the catheter while maintaining sterility. To prevent the catheter from breaking off in the pleural space on removal, holes should be no greater than one third the circumference of the catheter, spaced apart from each other, and have no rough edges. After thoracocentesis the modified catheter should be removed with care.

As much fluid is removed from the pleural space as is possible, except in animals with acute hemothorax. Respiratory distress in animals with hemothorax is often multifactorial (e.g., inadequate oxygen delivery, hypoventilation), and the blood within the pleural space can be resorbed. These animals benefit from restoration of oxygen-carrying capacity and blood volume, with thoracocentesis performed only as essential to allow lung expansion. Hemothorax may be diagnosed based on a history of acute trauma or rodenticide ingestion. Otherwise obtaining frank blood during thoracocentesis can also indicate a traumatic tap. Free blood in the pleural space is distinguished from a traumatic tap by the following: failure of the blood to clot, low packed cell volume relative to peripheral blood, and erythrophagocytosis identified by cytology.

Fluid retrieved from the pleural space should always be analyzed cytologically. Total cell count, protein quantitation, and examination of a concentrated slide preparation allow fluid to be classified as a transudate, modified transudate, septic or nonseptic exudate, or hemorrhagic effusion. Slides should be scrutinized for infectious agents or abnormal cell populations. Fluid is saved for further characterization as indicated by history, gross examination, or cytologic findings. If pyothorax is suspected, Gram staining is performed, and aerobic and anaerobic cultures are obtained. If chylothorax is among the differential diagnoses, fluid triglyceride concentrations are measured and

Box 153-1

Causes of Pleural Effusion That Are Managed Directly

- Heart failure (modified transudate or chyle)
 - Heartworm disease
 - Cardiomyopathy
 - Tricuspid insufficiency
 - Congenital heart disease
- Obstruction or thrombosis of cranial vena cava
- Hypoproteinemia (pure transudate)
 - Protein-losing enteropathy
 - Protein-losing nephropathy
 - Liver failure
- Feline infectious peritonitis (nonseptic exudate)
- Coagulopathy (hemorrhagic effusion)
 - Rodenticide deficiency
 - Factor deficiency
- Trauma (hemorrhagic effusion or chyle)
- Lung lobe torsion (nonseptic exudate or hemorrhagic effusion)
- Diaphragmatic hernia (modified transudate, nonseptic exudate, or hemorrhagic effusion)
- Pulmonary thromboembolism (modified transudate, nonseptic exudate, or hemorrhagic effusion)

compared with triglyceride concentrations in a serum specimen obtained at the time of thoracocentesis (effusate triglycerides are higher in chylothorax).

In addition to managing respiratory compromise, the cardiovascular and systemic needs of the animal are met, including fluid therapy for dehydration or shock or antibiotics for sepsis syndrome. A complete diagnostic evaluation is undertaken after stabilization. Test selection is based on the history, physical examination, and cytologic characteristic of the effusion. When a primary cause is identified that can be managed directly (see Box 153-1), thoracocentesis is performed as needed to maintain the comfort of the animal until the underlying problem has resolved. The remainder of this article addresses the management of specific causes of pleural effusions: pyothorax, chylothorax, neoplastic effusion, lung lobe torsion (LLT), and idiopathic pleural effusion.

PYOTHORAX

The diagnosis of pyothorax is confirmed by the identification of a septic exudate through thoracocentesis. The diagnosis is generally straightforward when pleural fluid has been obtained before the initiation of antibiotic therapy, with organisms often visible cytologically. If antibiotics have already been given, the effusion may have the characteristics of a nonseptic exudate. Gram staining is helpful for characterizing organisms before culture results are available. A mixed infection, with anaerobes and aerobes, is generally present.

Often no source of infection is identified, especially in cats. In some of these cases pulmonary infection or a puncture wound may be the initiating event. A foreign body is another cause of pyothorax and can interfere with the

successful medical management of the disease. Although pyothorax is often idiopathic in dogs, the potential for the presence of foreign material is of greater concern in dogs than in cats.

It is necessary first to stabilize patients that are presented with severe dehydration, electrolyte imbalances, or sepsis. Thoracocentesis is performed for diagnostic and therapeutic purposes. Intravenous fluids and antibiotics are administered. Antibiotic recommendations are discussed in later paragraphs.

The two key components of successful treatment for pyothorax are drainage and antibiotics. Routine supportive care is also indicated. Aggressive treatment is begun immediately after the diagnosis of pyothorax to minimize the formation of adhesions, which interfere with drainage and decrease the likelihood of successful medical management. Drainage is achieved through indwelling chest tubes. Intermittent thoracocentesis is not nearly as effective as draining through chest tubes but can be considered in animals in which euthanasia is the only other option.

One chest tube is placed initially. The tube should be as large as can fit between the intercostal spaces to reduce the risk of obstruction of the tube with fibrin. Thoracic radiographs are evaluated after removal of as much fluid as possible through the tube. If remaining effusion is minimal, one tube is sufficient for treatment. However, if effusion persists on the opposite side, a second tube should be placed immediately. Inadequate positioning of a chest tube can result in persistent fluid on the ipsilateral side. Repositioning or replacing the tube is warranted. The continued presence of fluid despite multiple attempts to improve tube placement is suggestive of adhesions. Medical management with tube drainage can be attempted for 2 to 3 days, but the continued presence of localized fluid is an indication for thoracotomy and surgical débridement. The bandage securing the chest tube must not restrict the patient's ability to expand its chest during inspiration.

Continuous or intermittent suction of the chest tubes can remove the exudate from the pleural space. Continuous suction offers the advantage of maximal drainage, whereas intermittent suction is simpler logistically. Continuous suction is provided with a suction pump attached to a collection system that collects retrieved fluid, controls suction pressure, and maintains a one-way closed system. Convenient disposable collection systems are available commercially (e.g., Thora-Seal III, Sherwood Medical). Continuous suction does not greatly decrease the time required to manage pyothorax. Frequent monitoring is necessary to detect any problems with the system. Any leaks between the pleural cavity and the water seal can be rapidly and silently fatal. The system must also be evaluated periodically for obstructions caused by kinking of the tube or clogging with fibrin and debris.

Intermittent suction by syringe can be used successfully as long as the period between drainage attempts is short. Initially suction should be performed every 2 to 4 hours. As the volume of fluid produced decreases, often within the first few days, the interval can be lengthened. Ideally arrangements should be made for drainage to

occur through the evening hours during the first 24 to 48 hours. If such arrangements are not feasible, the chest should be drained last thing in the evening and again first thing in the morning to minimize the time that fluid is allowed to accumulate.

Twice-daily lavage of the pleural space with sterile 0.9% saline helps maximize drainage. There is no obvious benefit from the addition of antibiotics, antiseptics, or enzymes. The addition of heparin (1500 units/100ml) to the lavage fluid may decrease fibrin formation. The chest is drained as thoroughly as possible. A maximal volume saline (10ml/kg of body weight) that has been warmed to body temperature is slowly infused into the chest. Less volume is used if discomfort is noted. The animal is rolled slowly from side to side for several minutes, and the fluid is then removed. The expected recovery is approximately 75% of the infused volume. Recovery of a greater volume of cloudy fluid may indicate that a pocket of exudate was reached. Recovery of much less volume suggests either pocketing of fluid in a region that is not getting adequate drainage through the existing tubes or severe dehydration. (Differentiation of these causes may be possible through ultrasonography.) It is important to maintain sterile technique whenever the system is opened to prevent the entrance of hospital-origin pathogens. Adapter ports are covered with sterile caps when not in use and wiped with alcohol or hydrogen peroxide before use.

Initial antibiotic selection is based on coverage for both gram-negative organisms and anaerobes. Culture and sensitivity data are used once they become available to make modifications in the treatment plan if a resistant organism is detected. Negative culture results can occur despite the presence of microorganisms and should not be used to exclude a diagnosis of pyothorax. Antibiotics are administered intravenously until the patient is alert and eating well; they are then given orally. Treatment with antibiotics is continued for 4 to 6 weeks after removal of the chest tube.

Amoxicillin with clavulanate (Clavamox, Pfizer Animal Health; 22mg/kg q8h orally [PO]) is effective against nearly all anaerobes and gram-positive organisms and many (although not all) gram-negative organisms. Since amoxicillin with clavulanate is not available for intravenous administration, ampicillin with sulbactam is used initially (Unasyn, Pfizer Roering). The drug is dosed based on the ampicillin component (22mg/kg q8h intravenously [IV]). Clindamycin (Antirobe, Pharmacia & Upjohn; 11mg/kg q12h) also has good activity against anaerobes, including *Bacteroides fragilis*, but a second drug must always be added to treat gram-negative organisms. Fluoroquinolones or aminoglycosides can be used. Fluoroquinolones are preferred because they can be administered safely for prolonged periods. Initial antibiotic therapy may need to be modified, based on clinical response and results of culture and susceptibility testing.

Special antibiotic considerations must be made if "sulfur granules" are visible grossly in removed pleural fluid or if branching filamentous organisms are seen cytologically, indicative of *Actinomyces* or *Nocardia* spp. Acid-fast staining can help characterize the organisms. Acid-fast organisms are assumed to be *Nocardia*, although some *Nocardia* do not stain positively. Otherwise the more common *Actinomyces* is assumed, pending results of culture.

The final diagnosis is made through culture, and special techniques are required if these organisms are suspected. *Actinomyces* spp. are generally susceptible to penicillin derivatives. *Nocardia* are less predictable; but prolonged therapy with trimethoprim-sulfa drugs, tetracyclines, or aminoglycosides can be tried. A recent retrospective study supports early surgical intervention in dogs with infection caused by *Actinomyces*, presumably because of its association with plant foreign bodies (Rooney and Monnet, 2002).

It is extremely important to monitor patients regularly to ensure that days are not being wasted while the system is not providing adequate drainage, to determine the time to remove the chest tubes, and to determine whether surgical exploration is needed. Attempts to save money by foregoing regular monitoring often result in added expense in lengthened hospital stays or complications. Lateral and ventrodorsal or dorsoventral thoracic radiographs are evaluated at least every other day. Pockets of fluid that persist or increase in size indicate the need for replacement of chest tubes or surgical intervention if tube placement has been optimized. The volume of fluid recovered is measured, and a slide of the effusion is examined microscopically every day. The chest tube can be removed when the fluid has resolved radiographically, the volume of fluid recovered decreases to approximately 2ml/kg of body weight per day, and signs of infection have resolved cytologically. Cytologic resolution is indicated by the absence of organisms. In addition, neutrophils decrease in numbers and lose their degenerative appearance, and macrophages appear. If these criteria for tube removal have not been met within 1 week of aggressive therapy, surgical exploration is considered.

Complete blood count and serum biochemical analysis are performed as indicated by the general condition of the animal. Electrolyte abnormalities are common until the patient is eating well.

Animals are discharged with oral antibiotics after removal of chest tubes. Reevaluation is indicated approximately 1 week after removal of the tubes and again approximately 1 week after discontinuation of antibiotics. Ideally an additional reevaluation occurs 1 month later. Thoracic radiographs are evaluated at these times. The purpose of these radiographs is to identify early recurrence of effusion. Early identification of recurrence greatly facilitates the ability of the surgeons to find a localized nidus of infection or foreign body. Thorough exploration of the chest cavity is extremely difficult, particularly in animals with a history of exudative disease. Localizing the disease provides a distinct advantage to the surgeon and increases the likelihood that a foreign body or nidus of disease can be found and removed.

Exploratory surgery is indicated for removal of a suspected foreign body or nidus of infection, for breakdown of adhesions when adequate drainage cannot be achieved, and for patients that do not show substantial improvement after 1 week of aggressive medical management. A sternotomy is performed so that both sides of the thorax can be accessed unless an obvious lesion is visible radiographically. Fibrin tags are broken down, grossly abnormal lung lobes are removed, and a search for foreign material is performed. As mentioned previously,

most foreign material is extremely difficult to identify at surgery. A chest tube is placed for continued drainage after thoracotomy. The tube is pulled with medical management based on the criteria described, usually after 1 to 3 days.

The prognosis for pyothorax is fair to good. Animals that receive aggressive treatment early in the course of disease can recover with no further complications. Most patients that do not survive either die or are euthanized during the first few days when they are systemically ill or the owner declines treatment. When a foreign body is present, recurrence is likely unless surgical removal of the affected lung lobe or tissue is accomplished. Initial conservative treatment of pyothorax with oral antibiotics alone or with occasional thoracocentesis most often leads to adhesions, necessitating surgical débridement.

CHYLOTHORAX

Management of animals with chylothorax has been greatly refined since the initial report of its surgical treatment in three dogs and one cat in 1958. However, the ability to effectively treat affected animals has been hindered by a lack of understanding of the etiology of this devastating disease. Appropriate treatment of affected animals depends foremost on confirming the diagnosis and defining the cause. Once the diagnosis has been made and concurrent diseases ruled out, the value of medical versus surgical treatment must be considered.

Although the prevalence of chylothorax is unknown, a recent survey of 2000 veterinary clinics regarding the diagnosis and treatment outcomes of dogs and cats presenting with chylothorax suggested that cats were diagnosed with chylothorax approximately four times more often than dogs.* Of 795 veterinarians or veterinary hospitals returning the survey, nearly 40% had diagnosed at least one dog or cat with chylothorax in a 5-year period; information regarding 76 dogs and 297 cats with chylothorax was contributed.

Chylothorax was previously thought to be caused by thoracic duct (TD) rupture secondary to trauma; however, this is now known to be a relatively rare cause of chylothorax. Although traumatic rupture of the TD may occur, in most of these animals the TD spontaneously heals, and clinical signs associated with chylothorax are not recognized. More commonly recognized causes in dogs and cats include right heart failure, mediastinal masses, pericardial disease, paroxysmal atrioventricular block, fungal granulomas, and heartworm infection. Unfortunately, in a majority of animals despite extensive diagnostic workups, the underlying etiology is undetermined (idiopathic chylothorax). Because treatment of this disease varies considerably, depending on the underlying etiology, it is imperative that clinicians identify concurrent disease processes before instituting definitive therapy.

Because any disease that results in high systemic venous pressures (e.g., cardiomyopathy, pericardial effusion, congenital cardiac abnormalities, and heartworm

disease) may cause chylothorax, a complete cardiac workup is warranted in affected animals. Treatment of animals with cardiomyopathy or congenital heart disease and chylothorax should be based primarily on palliation when necessary with thoracocentesis and improving cardiac output and decreasing venous pressures with appropriate drug therapy or interventions. If pericardial effusion is diagnosed, the underlying etiology should be determined, and pericardiectomy performed if indicated. Although heartworm infection is uncommon in felines, experimental infection with *Dirofilaria immitis* has been shown to result in chylothorax in a small number of cats. Naturally occurring heartworm disease has also been associated with chylothorax in cats. Therefore it is recommended that animals with chylothorax be screened for heartworm infection.

If an anterior mediastinal mass is identified, a fine-needle aspirate may be performed to determine the tumor or tissue type. Specific therapy (i.e., radiation therapy, chemotherapy, antifungal therapy, surgery) should then be instituted according to findings. In these animals the chylous effusion is probably secondary to compression of the cranial vena cava by the mass, and shrinkage of the mass may result in resolution of the pleural fluid. For prognostic purposes it is prudent to assess feline leukemia virus and feline immunodeficiency virus status in cats with mediastinal lymphosarcoma. In some animals with chylothorax the mediastinum and pericardium are thickened, associated with chronic irritation induced by chyle (Fossum et al., 2004). The pericardial thickening may lead to elevated right-sided venous pressures that may impede the drainage of chyle via lymphaticovenous communications after TD ligation.

When no obvious underlying disorder can be found, the term *idiopathic* chylothorax is used. Unfortunately management of animals with idiopathic chylothorax is difficult. Until the etiology of chylothorax in these animals is understood, therapy will remain palliative and less than optimal in many instances. One possibility is that in these animals increased volumes of lymph are being transported through the TD. These increased flows may occur secondary to abnormal right-sided venous pressures that cause much of the lymph that would normally be transported from the liver into the venous system to be shunted into the lymphatic system. It is possible that minimally elevated venous pressures, in association with other unknown factors, may be sufficient to substantially elevate lymphatic flows through the TD.

Clinical Signs/Signalment/History

Most animals with chylothorax present with a normal body temperature unless extremely excited or severely depressed. Additional findings in patients with chylothorax may include coughing, muffled heart sounds, depression, anorexia, weight loss, pale mucous membranes, arrhythmias, murmurs, and pericardial effusion.

Oriental breeds (i.e., Siamese and Himalayan) appear to have an increased prevalence of chylothorax. Although chylothorax may affect animals of any age, in one study older cats were more likely to develop chylothorax than young cats. This finding was believed to indicate an association

*Personal communication, Aguirre-Sanceledonio M, Fossum TW, 2005.

between chylothorax and neoplasia. Afghan hounds and Shiba Inu dogs are also thought to be predisposed to chylothorax.

Coughing is often the first (and occasionally the only) abnormality noted by owners until the animal becomes dyspneic. Many owners report that they first noticed coughing months before presenting the animal for veterinary care; therefore animals that cough and do not respond to standard treatment of nonspecific respiratory problems should be evaluated for chylothorax. Coughing may be a result of irritation caused by the effusion or related to the underlying disease process (i.e., cardiomyopathy, thoracic neoplasia).

Diagnosis

Animals that have collapsed lung lobes that do not appear to reexpand following removal of chyle or other pleural fluid should be suspected of having underlying pulmonary parenchymal or pleural disease such as fibrosing pleuritis. Diagnosis of fibrosing pleuritis is difficult. The atelectatic lobes may be confused with metastatic or primary pulmonary neoplasia, LLT, or hilar lymphadenopathy. Radiographic evidence of pulmonary parenchyma that fails to reexpand after removal of pleural fluid should be considered possible evidence of atelectasis with associated fibrosis. Fibrosing pleuritis should also be considered in animals with persistent dyspnea in the face of minimal pleural fluid.

Fluid recovered by thoracentesis should be placed in an ethylenediaminetetraacetic (EDTA) tube for cytologic examination. Placing the fluid in an EDTA tube rather than a "clot-tube" allows cell counts to be performed. Although chylous effusions are routinely classified as exudates, the physical characteristics of the fluid may be consistent with a modified transudate. The color varies, depending on dietary fat content and the presence of concurrent hemorrhage. The protein content is variable and often inaccurate because of interference of the refractive index by the high lipid content of the fluid. The total nucleated cell count is usually less than 10,000 and consists primarily of small lymphocytes or neutrophils, with lesser numbers of lipid-laden macrophages.

Chronic chylous effusions may contain low numbers of small lymphocytes because of the inability of the body to compensate for continued lymphocyte loss. Nondegenerative neutrophils may predominate with prolonged loss of lymphocytes or if multiple therapeutic thoracentesis have induced inflammation. Degenerative neutrophils and sepsis are uncommon findings because of the bacteriostatic effect of fatty acids, but they can occur iatrogenically because of repeated aspirations.

Pseudochylous effusion is a term that has been misused in the veterinary literature to describe effusions that look like chyle but in which a ruptured TD is not found. Given the known causes of chylothorax in dogs and cats, this term should be reserved for effusions in which the pleural fluid cholesterol is greater than the serum cholesterol concentration and the pleural fluid triglyceride is less than or equal to the serum triglyceride. Pseudochylous effusions are extremely rare in veterinary patients but may be associated with tuberculosis.

Chylothorax must be differentiated from other types of pleural effusion. Pyothorax may appear grossly similar to chylothorax, but the predominant cell type is a degenerative neutrophil in animals with infection of the pleural space. To help determine if a pleural effusion is truly chylous, several tests can be performed, including comparison of fluid and serum triglyceride levels, Sudan III stain for lipid droplets, and the ether clearance test. The most diagnostic test is comparison of serum and fluid triglyceride levels. If the effusion is truly chylous, it contains a higher concentration of triglycerides than simultaneously collected serum.

MEDICAL MANAGEMENT OF CHYLOTHORAX

If an underlying disease is diagnosed, it should be treated, and the chylous effusion managed by intermittent thoracentesis. If the underlying disease is treated effectively, the effusion often resolves; however, complete resolution may take several months. Surgical intervention should be considered in animals with idiopathic chylothorax or in those that do not respond to medical management. Chest tubes should only be placed in animals with suspected chylothorax secondary to trauma (very rare), when rapid fluid accumulation necessitates that thoracentesis be performed several times a week to prevent dyspnea, or after surgery. Electrolytes should be monitored since hyponatremia and hyperkalemia have been documented in dogs with chylothorax undergoing multiple thoracentesis (Willard et al., 1991). A low-fat diet may decrease the amount of fat in the effusion, which may improve the animal's ability to resorb fluid from the thoracic cavity.

Commercial low-fat diets are preferable to homemade diets; however, if commercial diets are refused, homemade diets are a reasonable alternative (Fossum, 2007). Medium-chain triglycerides (once thought to be absorbed directly into the portal system, bypassing the TD) are transported via the TD of dogs. Thus they may be less useful than previously believed. In addition, they are relatively unpalatable, and most cats and some dogs refuse to eat food to which they have been added. It is unlikely that dietary therapy will cure this disease, but it may help in the management of animals with chronic chylothorax. Clients should be informed that with the idiopathic form of this disease there is no effective treatment that stops the effusion in all animals. However, the condition may resolve spontaneously in some animals after several weeks or months.

Benzopyrene flavinoids such as rutin have been used for the treatment of lymphedema in humans for years and have been recommended for the treatment of chylothorax in cats. Although a small number of animals with chylothorax reportedly have resolved the effusion after treatment with this drug (Thompson, Cohn, and Jordan, 1999), the efficacy of rutin in the treatment of chylothorax is unproven. The recommended dosage is 50 to 100 mg/kg orally three times a day.

Somatostatin is a naturally occurring substance that has an extremely short half-life. It inhibits gastric, pancreatic, and biliary secretions (i.e., glucagon, insulin, gastric acid,

amylase, lipase, and trypsin) and prolongs gastrointestinal transit time; decreases jejunal secretion; and stimulates gastrointestinal water absorption. In recent years analogs of somatostatin have been used to successfully treat chylothorax in humans with traumatic or postoperative chylothorax. In these patients reduced gastrointestinal secretions may aid healing of the TD by decreasing TD lymphatic flows (Markham, 2000). It has also been reported to result in early decreased drainage and early fistula closure in dogs with experimental transection of the TD. The mechanism by which nontraumatic chylothorax may benefit from this treatment is unclear; however, resolution of pleural fluid has been reported in cats with idiopathic chylothorax in whom octreotide (Sandostatin, Novartis Pharmaceutical Corp.), has been administered.* Octreotide (10mcg/kg subcutaneously [SQ] three times a day for 2 to 3 weeks) is a synthetic analog of somatostatin that has a prolonged half-life and minimal side effects. Soft stools that resolve after withdrawal of the drug may occur. Prolonged treatment should be discouraged because in humans treatment for longer than 4 weeks has been associated with gallstone formation. I (TF) have used octreotide in two dogs; one with chylothorax and one with serosanguineous effusion after TD ligation. Although the latter dog resolved the effusion within a few days of treatment, the former case did not respond. The efficacy of octreotide in animals with chylothorax requires further investigation.

Fibrosing pleuritis is a life-threatening complication of chronic chylothorax, particularly in cats. In addition to chylothorax, pyothorax, feline infectious peritonitis, hemothorax, and tuberculosis have been associated with the development of fibrosing pleuritis. Although the cause of the fibrosis is unknown, apparently it can develop subsequent to any prolonged exudative or blood-stained effusion. Exudates are characterized by a high rate of fibrin formation and degradation. Fibrin formation probably increases because chronic inflammatory exudates such as chylothorax and pyothorax induce changes in mesothelial cell morphologic features, resulting in increased permeability, mesothelial cell desquamation, and triggering of both pathways of the coagulation cascade. These desquamated mesothelial cells have also been shown to produce type III collagen in cell culture, promoting fibrosis. In addition, the chronic presence of pleural fluid might lead to impairment in the mechanism of fibrin degradation. Fibrinolysis may decrease because direct injury to mesothelial cells may reduce inherent fibrinolytic activity of the cells and/or the increased fluid volume may dilute local plasminogen activator. Plasminogen activator converts the precursor plasminogen to its active form, plasmin. Fibrinolytic activity in mammals is attributable primarily to this serine protease. In animals with fibrosis the pleura is thickened by diffuse fibrous tissue that restricts normal pulmonary expansion. Pulmonary function testing in humans with fibrosing pleuritis have shown a decrease in vital capacity and static compliance, necessitating greater negative intrapleural pressures for any given change in lung volume when compared with healthy patients.

SURGICAL TREATMENT OF CHYLOTHORAX

Surgical intervention is warranted in animals that do not have underlying disease and in whom medical management becomes impractical, and the approaches I (TWF) advocate are summarized in the following paragraphs. Medical management becomes impractical when thoracentesis is required more frequently than once a week or when repeat thoracentesis fails to relieve the dyspnea. Surgical options include mesenteric lymphangiography and TD ligation, subtotal pericardiectomy, omentalization, passive pleuroperitoneal shunting, active pleuroperitoneal or pleurovenous shunting, and pleurodesis. Of these only the first two (TD ligation and pericardiectomy) are recommended as first-line therapies. Pericardiectomy also may effectively treat or even prevent the serosanguineous effusions that occasionally occur after TD ligation in some animals.

In a recent study TD ligation with pericardiectomy was performed in 17 animals, and pericardiectomy alone was performed in 3 additional animals that presented over a 5.5 year period to one institution (Fossum et al., 2004). Nineteen animals presented for evaluation of idiopathic chylothorax (9 dogs, 10 cats), and 1 dog presented for serosanguineous pleural fluid after TD ligation that had been performed elsewhere. Clinical signs of pleural fluid resolved in 10 of 10 dogs and 8 of 10 cats after surgery. The overall success rate for surgical treatment of chylothorax (i.e., resolution of pleural fluid) in this study was 90% (100% in dogs and 80% in cats). These data suggest that TD ligation in conjunction with pericardiectomy has a favorable outcome in animals with idiopathic chylothorax.

The only effective treatment for fibrosing pleuritis is decortication; however, the indications and value of decortication in animals are unknown. Decortication may give the best functional result when the pleuritis is of short duration and pulmonary parenchymal disease is minimal. In such cases the thickened pleura is not firmly adherent to the underlying parenchyma and can be removed without severely damaging the underlying lung; however, pneumothorax is a common sequelae and usually requires tube thoracentesis. Decortication in humans carries a good prognosis if only one or two lobes are involved; however, when the fibrosis is diffuse, as occurs in many animals with chylothorax, even with effective decortication a guarded prognosis is warranted. When more than one lung lobe is decorticated, reexpansion pulmonary edema may occur and is often fatal. If decortication is successful, lung expansion and pulmonary function may improve over a 2- to 3-month period. In a recent study several animals were reported to have severe fibrosing pleuritis despite the owners' claims that the clinical signs had been of recent onset (Fossum et al., 2004). In that study decortication was deemed necessary in two cats because the extent of the pleuritis was such that it was thought that respiratory distress might still be present after surgery, even if the pleural fluid resolved. Both of these cats developed severe pneumothorax and required prolonged intensive management of this condition. One cat was determined to have

*Personal communication, Gretchen Sicard.

a tracheal rupture that healed spontaneously over a 2-week period. Neither cat developed reexpansion pulmonary edema after decortication; thus decortication may be of value in animals with severe fibrosing pleuritis in which increased lung expansion is deemed important. Owners must be cautioned about the increased morbidity and mortality associated with this condition, particularly with the development of reexpansion pulmonary edema. Duration of clinical signs appears to be a highly unreliable predictor of the success of surgery or the extent of fibrosing pleuritis in animals with chylothorax. Many owners simply do not recognize clinical signs of chylothorax until the disease is well advanced. In these animals fluid production may be offset by fluid resorption for months; thus clinical signs are mild until sufficient pleural thickening occurs that fluid resorption is diminished or eliminated completely. It is important to note that the degree of fibrosing pleuritis does not appear to warrant a poor prognosis. I have operated on cats with severe fibrosing pleuritis that later appear clinically normal once the effusion stops.

Thoracic Duct Ligation With Mesenteric Lymphangiography

Thoracic duct ligation is performed in cats from a left lateral intercostal thoracotomy or transdiaphragmatically. In dogs the ligation is performed from a right intercostal thoracotomy. The mechanism by which TD ligation is purported to work is that following TD ligation abdominal lymphaticovenous anastomoses form for the transport of chyle to the venous system. Therefore chyle bypasses the TD, and the effusion resolves. Advantages of TD ligation are that, if it is successful, it results in complete resolution of pleural fluid (as compared to palliative procedures described in the following paragraphs) and may prevent fibrosing pleuritis from developing. The disadvantages include that operative time is long, which is problematic in debilitated animals; there is a high incidence of continued or recurrent chylous or nonchylous (from pulmonary lymphatics) effusion; and mesenteric lymphangiography is often difficult to perform (particularly in cats). Without mesenteric lymphangiography, complete ligation of the TD cannot be ensured; however, lymphangiography in cats might not be uniformly successful in verifying complete ligation of the TD. In addition, some animals may form collateral lymphatics past the site of the ligature and thus reestablish TD flow. If chyle flow is directed into the diaphragmatic lymphatics, chylothorax may continue or recur.

For lymphangiography, food is withheld 12 hours before surgery. The left side of the thorax in cats (right side in dogs) and the abdomen, or just the abdomen if a midline celiotomy is being performed, is prepared for aseptic surgery. If a thoracic approach to the TD is used, a paracostal incision is made to exteriorize the cecum. Once the cecum has been exteriorized, a lymph node adjacent to the cecum is located. A small volume (0.1 to 1 ml) of methylene blue (USP 1%, American Quinine) diluted with saline to a light-to-medium blue color may be injected into the lymph node to increase visualization of lymphatics. Repeated doses of methylene blue should be

avoided because of the risk of inducing Heinz body anemia or renal failure. Careful dissection of the mesentery near this node allows large lymphatic vessels to be visualized and cannulated with a 20- or 22-gauge over-the-needle catheter. Cannulation of this lymphatic is more difficult in cats than in dogs because cats have more fat in their mesentery and their lymphatics are significantly smaller. Two sutures (4-0 silk) are placed in the mesentery and used to secure the catheter and an attached piece of extension tubing in place (the ends of the suture can be looped over the hub of the extension tubing). An additional suture may be placed around the extension tubing and through a segment of intestine to prevent dislodgement of the catheter. A three-way stopcock is attached to the end of the extension tubing, and a water-soluble contrast agent is injected at a dose of 1 ml/kg diluted with 0.5 ml/kg of saline. A lateral thoracic radiograph is taken while the last millimeter is being injected. This lymphangiogram can be used to help identify the number and location of branches of the TD, which need to be ligated, and it can be repeated following ligation to help determine the extent of lymphangiectasia present in the cranial thorax.

Typically the TD is approached via caudal intercostal thoracotomy (9th to 12th intercostal space) or via an incision in the diaphragm. Once the duct has been located, hemostatic clips can be used to ligate it. The advantage of using hemoclips (Edward Weck and Co. Inc.) is the reference point created for subsequent radiographs if further ligation is necessary. In addition, a nonabsorbable suture such as silk is also placed around the duct. Visualization of the TD can be aided by injecting methylene blue into the lymphatic catheter. If a catheter was not placed, the dye can be injected into a mesenteric lymph node, although this results in inferior visualization of the TD. Pericardiectomy may be performed from the same intercostal thoracotomy in most animals. If the pericardium cannot be reached, a second more cranial intercostal thoracotomy may be necessary.

Active Pleuroperitoneal or Pleurovenous Shunting

Active pleuroperitoneal or pleurovenous shunting (Denver double valve peritoneous shunt, Denver Biomaterials Inc.) has been recommended for the treatment of chylothorax in dogs and cats and may be a reasonable consideration in animals in which all other therapies have failed. Commercially made shunt catheters are available and can be used to pump fluid from the thorax to the abdomen. Under general anesthesia a vertical incision is made over the middle of the fifth, sixth, and seventh ribs. A purse-string suture is placed in the skin at this site; and, following the placement of fenestrations in the venous end of the shunt catheter, the catheter is bluntly inserted into the pleural space. A tunnel is created by blunt dissection under the external abdominal oblique muscle, and the pump chamber is pulled through the tunnel. The efferent end of the catheter is then placed into the abdominal cavity through a preplaced purse-string suture and incision located just caudal to the costal arch. The shunt

must be placed with the pump chamber directly overlying a rib so that the chamber can be compressed effectively. Complications associated with pleuroperitoneal or pleurovenous shunts include: (1) the shunts are expensive; (2) they may easily occlude with fibrin; (3) some animals do not tolerate compression of the pump chamber; and (4) they require a high degree of owner compliance and dedication. In addition, thrombosis, venous occlusion, sepsis, and electrolyte abnormalities have been reported in humans.

Omentalization

Omentalization has been described as a technique to treat animals with chylothorax when other surgical treatments are not successful or deemed impossible. A fifth- or sixth-space intercostal thoracotomy is made to provide access to the cranial thorax. A paracostal incision is then made so that a dorsal omental pedicle flap can be raised. The omental flap is brought through an incision in the pars costalis of the diaphragm. Care should be taken to avoid rotation of or excessive tension on the omental pedicle. The omentum is spread out within the thorax to provide a large surface area. An omentopexy is performed by using synthetic absorbable suture to anchor the omentum to the mediastinum in the region of the lymphaticovenous anastomoses between the TD and the cranial vena cava. Sutures should be placed so that they do not interfere with the blood supply of the omentum. The success of this technique is unproven, and I (TWF) do not routinely recommend it.

Other Treatments

Passive pleuroperitoneal shunting has been recommended as treatment of chylothorax in cats, but this technique is no longer recommended. The goal of placing a fenestrated silastic sheet in the diaphragm was to allow drainage of the chylous fluid into the abdomen where the fluid could be resorbed by visceral and peritoneal lymphatics, thereby alleviating the respiratory distress and need for subsequent thoracentesis. This technique may be ineffective, and chronic irritation of the sheeting may be associated with neoplastic transformation of tissues.

Pleurodesis is the formation of generalized adhesions between the visceral and parietal pleura. Adhesions may occur spontaneously in association with pleural effusion, or in some species they can be induced following instillation of an irritating substance into the pleural cavity. This technique has been recommended for the treatment of chylothorax in dogs and cats, but I (TWF) do not recommend it. For pleurodesis to be successful the lungs must be able to contact the body wall; however, many animals with chronic chylothorax have some thickening of their visceral pleura, which prohibits normal lung expansion (see fibrosing pleuritis in previous paragraphs). Neither mechanical (surgical) pleurodesis or talc administration resulted in pleurodesis in experimental dogs; however, thickening of the pleura did occur in some animals. Chemical or surgical pleurodesis is unlikely to be successful in animals with chylothorax.

NEOPLASTIC EFFUSION

Any intrathoracic neoplasia potentially can result in pleural effusion through obstruction to lymphatic or venous drainage, inflammation, secondary infection, or hemorrhage. Effusion is most often associated with mediastinal lymphoma, pleural mesothelioma, and metastatic carcinoma.

Mediastinal lymphoma is a common tumor of cats and is treated with combination chemotherapeutic protocols as recommended for multicentric lymphoma. Response is often dramatic, with significant resolution of respiratory difficulties in 48 to 72 hours. Pending response, thoracentesis is used to remove as much fluid from the thorax as possible. Stress is minimized, and an oxygen-enriched environment or nasal oxygen is provided as needed. Local radiation therapy can be administered when available and provides a similarly rapid response. Rates of remission as high as 92%, with durations as long as 29 months (median 6 months), have been reported for cats receiving combination chemotherapy (Cotter, 1983).

Remission is less likely in animals with mesothelioma and carcinoma involving the pleural surfaces. However, clinical signs in dogs sometimes can be relieved for prolonged periods through control of effusion with palliative therapy using intracavitary cisplatin (American Pharmaceutical Partners) with or without additional systemic treatment. Moore, Kirk, and Cardona (1991) reported resolution of pleural effusion in four dogs treated with intracavitary cisplatin. Effusion resolved in three dogs after one intracavitary treatment and in the fourth dog after two treatments. Recurrence of effusion ranged from 129 to longer than 306 days in a dog still alive and free of effusion at the time of the report. Two other dogs subsequently treated by the same author had decreased volumes, but not resolution, of effusion (Moore, 1992).

Cisplatin is able to reach high concentrations in tissues within a few millimeters of the contact surface. It is most likely to be effective in controlling effusion before actual nodules have formed. Systemic chemotherapy can be administered in addition to intracavitary treatment to reach the interior of larger, vascularized nodules. Cisplatin placed within the pleural cavity is absorbed systemically; if combined with systemic chemotherapy, dosages need to be adjusted to avoid significant toxicity.

The protocol for intracavitary delivery of cisplatin is not difficult. Dogs are administered 0.9% sodium chloride intravenously for 4 hours before treatment and for 2 to 4 hours after treatment at a rate of 10 ml/kg/hour. Cisplatin is given at a dose of 50 mg/m² diluted in 0.9% sodium chloride to a total volume of 250 ml/m². The solution is warmed to body temperature before administration. A 16-gauge over-the-needle catheter is placed into the pleural space using sterile technique, and as much fluid as possible is removed. Cisplatin is infused slowly into the pleural space through the same catheter, and the catheter is removed. Treatments were scheduled every 4 weeks in the study by Moore, Kirk, and Cardona (1991), and sometimes additional systemic treatment was given. The current protocol being used at our institution is to administer intracavitary carboplatin every 3 to 4 weeks as needed to control effusion. If the effusion resolves

completely, intracavitary therapy is discontinued after the fourth treatment. Intracavitary therapy is reinstituted if effusion recurs.

Nonlymphomatous malignant effusions are rare in cats, and standard treatment has not been established. Cisplatin is not recommended for administration in cats because of acute pulmonary toxicity. Carboplatin has not been associated with pulmonary toxicity and has the potential to be effective as an intracavitary infusion.

Pleurodesis has been proposed to control malignant effusions in dogs and cats. Unfortunately a consistently effective technique has not been established (see section on Chylothorax earlier in the chapter).

The therapeutic response to any of these palliative measures is based primarily on clinical response, with the goal of therapy being a good quality of life with normal respiratory efforts. Thoracic radiographs can be taken for objective determination of progress. Animals with slowly forming effusion can be further managed with intermittent thoracocentesis. Placement of pleuroperitoneal shunts may provide symptomatic relief to patients requiring frequent thoracocentesis. By creating a path for pleural fluid to cross into the abdominal cavity, more space is available within the thoracic cavity for expansion of the lungs. Pleuroperitoneal shunts were discussed previously.

LUNG LOBE TORSION

LLT is a rotation of the lung lobe along its long axis, with twisting of the bronchus and pulmonary vessels at the hilus. Any mechanism that increases mobility of a lung lobe seems to favor development of torsion. Partial collapse of the lung (i.e., with pulmonary disease or trauma) frees it from its normal spatial relationships with the thoracic wall, mediastinum, and adjacent lung lobes and they may enhance mobility. Pleural effusion or pneumothorax, along with subsequent atelectasis of lung lobes, can allow increased movement of a lobe, predisposing to torsion. Although LLT has been reported to cause chylothorax in dogs, it is more likely that the chylothorax caused the LLT. LLT has been reported secondary to previous thoracic surgery, in which lung lobes are manipulated and may remain partially collapsed after thoracic closure.

Torsion of a lung lobe results in venous congestion of the affected lobe; however, the arteries remain at least partially patent, allowing blood to enter. As fluid and blood enter the alveoli, lung consolidation occurs, and the lobe becomes dark colored and firm, similar in shade to the liver. The shape of the affected lobe is often altered, and it may appear displaced from its normal location within the thorax radiographically. Pleural fluid usually accumulates because of continued venous congestion.

Clinical Signs/Signalment/History

Deep-chested large-breed dogs, especially Afghan hounds, are more commonly affected. LLT in Afghan hounds may be associated with chylothorax. In large breeds LLT has been reported to occur spontaneously, without previous history of disease or trauma. LLT has also been reported in small breeds, including pugs, but is usually secondary to primary pleural effusion, thoracic surgery,

or trauma. It is rare in cats. Middle-aged dogs are more commonly affected, but LLT may occur in animals of any age. Affected animals usually have moderate-to-severe respiratory distress. Pleural effusion is consistently present in animals with LLT; therefore findings often include muffled heart and lung sounds. Other findings may include depression, anorexia, coughing, fever, dyspnea, hemoptysis, hematemesis, and/or vomiting.

Diagnosis

Thoracic radiographic changes are variable, depending on the volume of pleural fluid, presence or absence of pre-existing disease, and duration of the torsion. The most consistent finding is the presence of pleural effusion accompanied by an opacified lung lobe. Initially air bronchograms are present in the torsed lobe and can be seen extending toward the abdomen. Air bronchograms eventually disappear as fluid and blood fill the bronchial lumen. The presence of a noninflated, radiopaque lung lobe that persists after removal of pleural fluid should increase suspicion for LLT. Positional radiographs using horizontal beam x-rays (lateral decubitus or upright ventrodorsal) are often helpful. Pleural fluid secondary to LLT may persist around the affected lobe rather than fall to the dependent side. Failure of the lobe to reinflate in the “up” or nondependent hemithorax is another indication of LLT. Ultrasonography or computed tomography may also allow confirmation of a LLT prior to surgery. The right middle lung lobe is the most commonly torsed lobe in dogs.

Laboratory findings with LLT are variable. Fluid analysis may reveal a sterile, inflammatory effusion or chyle; or the fluid may be bloody. However, pleural effusion of any etiology can initiate a secondary LLT, making results of pleural fluid analysis variable and confusing. The appearance of blood in a previously nonhemorrhagic pleural fluid may indicate occurrence of LLT. An inflammatory leukogram may be present; however, changes in the leukogram may reflect the initial disease process rather than the LLT.

MEDICAL MANAGEMENT

Initial therapy is aimed at stabilizing the animal and alleviating respiratory distress before surgery. Thoracocentesis should be performed to remove pleural fluid. Persistent or massive pleural effusion may require placement of a chest tube. Oxygen therapy given by oxygen cage or nasal insufflation is beneficial to some animals. Underlying diseases such as pneumonia should be identified and treated with appropriate antibiotic therapy. Intravenous fluid therapy is beneficial before and during surgery to maintain hydration.

SURGICAL TREATMENT

Spontaneous correction of a torsed lung lobe is uncommon because of swelling of the lobe and rapid formation of adhesions. The treatment of choice for LLT is lobectomy of the affected lobe. Unless LLT is diagnosed very quickly (i.e., immediately after a surgical procedure), damage to the pulmonary parenchyma is generally severe enough that attempts to salvage the lobe are not warranted. Recurrence

has been reported following surgical correction in which lobectomy was not performed. The prognosis is good for most animals with LLT if surgery is performed; however, animals have developed LLT in another lobe after surgery. Pleural effusion (unless it is chylous in nature) usually resolves within a few days of surgery.

IDIOPATHIC PLEURAL EFFUSION

A clinical diagnosis of idiopathic pleural effusion is made after complete diagnostic evaluation fails to identify a primary cause. The general diagnostic approach has been described earlier in the section on Initial Management of Pleural Effusion. Note that specific tests are required to identify the etiologies listed in Box 153-1. Although not strictly idiopathic, in our experience the most common cause of clinically diagnosed idiopathic effusion is occult neoplasia. Ultrasonography and computerized tomography are more sensitive than radiography in suggesting a diagnosis of neoplasia. Ultrasonography is best performed while effusion is present. In other cases or to confirm ultrasonographic findings, thoracoscopy or thoracotomy with gross examination and biopsy of pleura and lungs may be necessary to confirm a diagnosis of neoplasia. Another potential occult cause of apparently idiopathic effusion is infection with organisms that are not identified through routine cytologic or microbiologic methods, such as with occult mycobacteriosis. Thus a trial course of azithromycin can be considered (5 to 10 mg/kg q24h PO for 7 days and then q48h for 5 weeks).

Palliative treatment for patients with idiopathic pleural effusion begins with intermittent thoracocentesis. If it is difficult to remove the effusion adequately with routine thoracocentesis, ultrasound guidance may prove useful in identifying localized regions of fluid accumulation and directing needle or catheter placement. Corticosteroids and/or other immunosuppressive drugs have been successful in reducing the rate of fluid accumulation in some animals (but not all) with idiopathic pleural effusion. Pleuroperitoneal shunts are placed in patients that require frequent thoracocentesis to allow comfortable breathing (see section on Chylothorax earlier in the chapter).

Pneumothorax

AMY K. VALENTINE, *Springfield, Oregon*
DANIEL D. SMEAK, *Columbus, Ohio*

Pneumothorax is the accumulation of air within the pleural space. The air source usually results from disruption of the thoracic wall, bronchial tree, pulmonary parenchyma, or esophagus, caused by injury or disease. Clinical signs of pneumothorax depend on the amount and rate of pleural air accumulation; but, when severe, signs may include tachypnea, dyspnea, abdominal breathing, or cyanosis. Affected animals compensate for reduced tidal volume by increasing frequency of ventilation, thus maintaining minute volume. Auscultation reveals diminished lung sounds, clear heart sounds, and increased resonance with percussion. Radiographic features of pneumothorax include air density within the pleural space, retraction of lung edges from the thoracic wall and diaphragm, and displacement of the cardiac silhouette away from the sternum on the lateral view. Pneumothorax causes decreased lung expansion with subsequent ventilation-perfusion mismatch, hypoxemia, and loss of intrapleural pressure gradients that impair the thoracic pump and venous return. These changes ultimately result in reduction of ventilatory capacity and cardiac output. Pneumothorax may be classified based on cause (traumatic or spontaneous) and pathophysiology (open or closed, simple or tension).

TRAUMATIC PNEUMOTHORAX

Traumatic pneumothorax, the most common type of pneumothorax in the dog, occurs in nearly half of all traumatic chest injuries (Kramek and Caywood, 1987). Traumatic pneumothorax is classified as open when it involves a penetrating injury to the chest wall as with a bite or stab wound, gunshot, or shearing injury. A closed traumatic pneumothorax usually is associated with blunt trauma resulting in laceration of the trachea, bronchial tree, or pulmonary parenchyma. Simple, closed pneumothorax is characterized by *nonprogressive* loss of intrapleural negative pressure. In contrast, tension pneumothorax develops when a disrupted airway, lung parenchyma, or chest wall functions as a one-way valve. This leads to *progressive* air leakage and elevation in intrapleural pressure, causing rapid deterioration of the patient.

Management

Management of traumatic pneumothorax is predicated on multiple factors, including the volume, source, and flow of air within the intrapleural space; the clinical condition of the patient; the severity of concurrent injury; and the availability of critical care resources. The most important means of stabilizing a patient in distress with

pneumothorax, regardless of the cause, is evacuating free pleural air and reestablishing normal thoracic pressure gradients. This may be accomplished by various techniques, including closure of thoracic wall defect(s), thoracentesis (Fig. 154-1), tube thoracostomy (Fig. 154-2) with intermittent or continuous suction (Fig. 154-3), or a Heimlich flutter valve (Salci et al., 2005). Thoracentesis is usually performed as the initial treatment for pneumothorax since it is the simplest, least invasive means of pleural evacuation. Placement of a thoracostomy tube is indicated if the pneumothorax recurs rapidly, when persistent air leakage is anticipated, or if thoracentesis is unsuccessful in reestablishing negative intrapleural pressure. In cases in which air accumulation is so rapid that intermittent suction does not relieve respiratory distress,

Fig. 154-1 Thoracentesis technique. A 20-gauge hypodermic needle or teat cannula is inserted into the eighth or ninth intercostal space in the upper half of the thoracic cage. Negative pressure is applied with a large syringe attached to an extension tube and a three-way stopcock. The collected air is expelled from the syringe by closing the stopcock to the patient and evacuating the syringe through the free open port on the stopcock (this process is repeated until no air remains in the pleural space).

Fig. 154-2 Thoracostomy tube placement. **A**, A small skin incision is created in the dorsal one third of the 10th intercostal space. The tube is tunneled subcutaneously two intercostal spaces and inserted in the eighth intercostal space. It is then advanced cranioventrally to the level of the second rib. It is initially clamped to prevent further pleural air accumulation, connected to an adapter and stopcock for pleural aspiration, and finally fixed to the skin with suture. **B**, Placement of a thoracostomy tube with forceps. A small skin incision is made, and the forceps (with the tube grasped in the tips) is bluntly pushed through the subcutaneous, penetrating the eighth intercostal space. The forceps are spread open to release the tube and feed it into the cranial thorax. Alternately the loose skin can be pulled cranially several inches by an assistant, an incision is made directly over the eighth space, and the tube is inserted directly downward into the pleural space. Once the tube is advanced into the thorax, the skin is released, creating a tunnel and causing the tube to exit from the skin caudally. **C**, Placement of a trocar thoracostomy tube. The tube with stylet is inserted through a small skin incision, and the tube is advanced bluntly through the subcutaneous tissue to the middle of the eighth intercostal space. The flanged end is held with the dominant hand, with the thumb placed over the stylet to hold it firmly in place. **D**, The less dominant hand grasps the tube within an inch or two of the sharp tip. As progressive downward pressure is placed on the tube, it is "hinged" up to a perpendicular position. The hand at the flanged end drives the tube into the pleural space, and the hand holding the tube close to the tip functions as a guard against excessive trocar penetration. The stylet is removed as the tube is advanced to the cranioventral thorax. **E**, The tube is secured to the dog with a single purse-string suture placed within 5 mm of the skin incision. Either the free ends from the purse-string knot are used to hold the tube or a separate skin bite (shown) is taken adjacent to the knotted purse-string suture, and the suture is crisscrossed and knotted four to five times to produce a friction knot without occluding the tube lumen.

Fig. 154-3 Three-bottle continuous pleural evacuation system. The chest tube is securely attached to a long flexible tubing and connected to a bottle serving as a *fluid trap*. The fluid trap is attached to a bottle serving as an *air trap* with an air vent tube submerged in 1 to 2 cm of water (to prevent air from being drawn into the thorax if a leak were to occur within the last two bottles of the system). The air trap is connected to the *pressure regulator* bottle with an air vent tube submerged in water. The level of submersion of the air vent tube in the third bottle determines the amount of pleural suction (this should not exceed 15 to 20 cm of water). The third tube in the regulator bottle is connected to a suction system. Commercially available systems possess the same functions as the three-bottle system displayed, but they are contained within a small portable unit.

continuous suction should be instituted. Additional therapies may include supplemental oxygen, mild sedation, analgesics, intravenous fluids, and intravenous antibiotics, depending on the overall condition of the patient.

Open Pneumothorax

The thoracic wound is closed immediately with a clean cloth, bandage, or glove during initial patient evaluation and transportation to the treatment area. The wound is inspected briefly; the area surrounding it is clipped free of hair and debris; and a sterile, occlusive bandage with abundant amounts of antiseptic ointment is applied to seal the wound. Immediate thoracocentesis is performed to evacuate air from the intrapleural space if the dog is dyspneic. Tube thoracostomy with intermittent or continuous suction should be considered if the pneumothorax progresses after initial thoracocentesis. Thorough wound débridement and reconstruction can be performed once the patient has been stabilized and anesthetized under more controlled, sterile conditions.

Simple Pneumothorax

Simple pneumothorax, if not too severe, usually responds well to conservative management. Bilateral thoracocentesis is performed if there is clinical indication based on tachypnea (especially if the respiratory rate exceeds 80 breaths/minute), dyspnea, or hypoventilation (cyanosis, abnormal

arterial blood gas measurements, or decreased oxygen saturation). Most pleural injuries seal within hours after thoracocentesis and cage rest are instituted. Patients should be kept quiet, and ventilatory rate and pattern monitored closely for several days to detect recurrence or progression of pneumothorax.

Tension Pneumothorax

Tension pneumothorax, regardless of etiology, causes severe pathophysiologic consequences and can be rapidly fatal. Dogs with tension pneumothorax have severe and progressive dyspnea and distress, weakness, shallow respirations, abdominal breathing, and a barrel-shaped chest wall. Thoracic radiographs reveal a large amount of free air with flattening and displacement of the diaphragm caudally. Treatment should be rendered quickly and should include immediate thoracocentesis followed by tube thoracostomy with intermittent or continuous suction. A flutter (Heimlich) valve may be used as an alternative to continuous suction; however, efficacy of the valve may be decreased by blood or effusion or in dogs weighing less than 15 kg (Orton, 1993). An exploratory thoracotomy for definitive treatment should be considered only after these measures have failed to stabilize the animal. It is often difficult at surgery to identify the site of traumatic injury causing the pneumothorax, and general anesthesia puts the dog at additional risk. If surgery is indicated, a median sternotomy is the preferred surgical approach for complete thoracic exploration since it allows visualization of both sides of the thorax (Bjorling, 1994).

Esophageal Perforation

Pneumothorax associated with esophageal perforation is usually caused by direct trauma or mucosal erosion from a sharp, intraluminal foreign body. Other etiologies may include gunshot injury, bite wound, or iatrogenic injury during endoscopic procedures. Pneumothorax from thoracic esophageal injury is often accompanied by pneumomediastinum and an inflammatory pleural effusion. Diagnosis of the perforation is confirmed using endoscopy or positive contrast radiography with an organic (iodinated) contrast agent. Medical treatment for esophageal perforation is discussed elsewhere (Johnson and Sherding, 1994; Kyles, 2003). Pneumothorax and pleural effusion are treated initially with chest tube drainage. Thoracotomy for esophageal surgery is reserved for significant esophageal injury or when esophageal healing is not progressing despite appropriate medical management. The severity of esophageal injury is usually based on subjective evaluation of the perforation, including the size of the defect, the health of the esophageal tissue around the defect, and evidence of focal versus generalized esophageal leakage of fluid or air (Johnson and Sherding, 1994).

SPONTANEOUS PNEUMOTHORAX

Spontaneous pneumothorax is defined as accumulation of air within the pleural space that is not associated with traumatic injury to the respiratory tract or chest wall. In contrast to traumatically induced pneumothorax, spontaneous pneumothorax is rare in dogs. Siberian huskies were overrepresented in one report (Puerto et al., 2002). Secondary spontaneous pneumothorax can stem from

Fig. 154-4 Excised cranial lung lobe from a dog with primary spontaneous pneumothorax. The *white arrow* points to an intact pulmonary bleb. The *dashed circle* contains a ruptured (upper left) and an intact bullae (lower right).

respiratory tract rupture caused by an underlying lung disease such as parasitism (e.g., paragonimiasis), bacterial pneumonia, neoplasia, and pulmonary abscess. Primary spontaneous pneumothorax is caused by rupture of idiopathic pulmonary blebs or bullae (Fig. 154-4). Pulmonary blebs are defined as localized accumulation of air within the visceral pleura, whereas pulmonary bullae are confluent alveoli. Ruptured subpleural blebs in conjunction with bullous emphysema have been reported as the most common cause of spontaneous pneumothorax in dogs; however, 50% of the cases in one study had underlying (nonemphysematous) lung disease. Management and prognosis for spontaneous pneumothorax are determined in part by the underlying cause (Valentine et al., 1996). Approximately one third of dogs with spontaneous pneumothorax have tension pneumothorax (Holtzinger et al., 1993).

A general diagnostic protocol to identify underlying disease is recommended and should include a complete blood count, serum chemistry profile, examination for *Dirofilaria*, fecal flotation and sediment examination, and thoracic radiography. Serial evaluation of thoracic radiographs may be necessary after chest evacuation to help identify occult pulmonary disease. Computed tomography (CT), bronchoscopy, and thoroscopy represent advanced procedures for identification of pulmonary lesions responsible for pneumothorax (Lipscomb, Hardie, and Dubielzig, 2004; Au et al., 2006).

Initial management of spontaneous pneumothorax is similar to the previous discussion on management of traumatic pneumothorax. Thoracentesis is routinely performed and followed by tube thoracostomy if clinically significant pneumothorax recurs. If intermittent pleural evacuation is unsatisfactory, continuous suction should be administered to alleviate respiratory distress.

Secondary Spontaneous Pneumothorax (Underlying Parenchymal Disease)

Management of underlying pulmonary disease is important for appropriate treatment of dogs with secondary spontaneous pneumothorax. Parasitic disease such as

dirofilariasis or paragonimiasis should be treated medically; the pneumothorax usually responds well to conservative (chest drainage) therapy (Valentine et al., 1996). Underlying pneumonitis caused by foreign body (plant material) migration has a good prognosis for long-term resolution following lung lobectomy (Puerto et al., 2002). Underlying metabolic disease resulting in secondary pulmonary parenchymal or microvascular pathology may be refractory to treatment and therefore associated with a poorer prognosis for recovery and long-term survival (Valentine et al., 1996). Pulmonary masses documented with thoracic radiographs may be further defined with CT or magnetic resonance imaging, ultrasonography (difficult with the presence of free pleural air), bronchoscopy, fine-needle aspiration and cytologic studies, or exploratory thoracotomy. Prognosis and specific therapy are predicated on the diagnosis. The mortality rate for dogs with spontaneous pneumothorax from confirmed neoplasia has been reported to vary from 50% (Puerto et al., 2002) to 100% (Valentine et al., 1996). These high mortality rates include a 50% euthanasia rate following diagnosis of the primary or metastatic neoplasm. Spontaneous pneumothorax related to bacterial or fungal pneumonia or pulmonary abscess rupture has been associated with mortality rates as high as 80% (Valentine et al., 1996).

Primary Spontaneous Pneumothorax (Bullous Emphysema)

A presumptive diagnosis of bullous emphysema should be considered if no other pulmonary disease can be identified after the general diagnostic screen (listed earlier) is performed. Radiographic confirmation of pulmonary bullae in dogs is highly unreliable since most bullae that have ruptured and are actively leaking are not visible on plain radiographs. CT scanning may be useful for diagnosis and presurgical assessment of pulmonary bullae or blebs, but overall efficiency and predictive values for CT in dogs remain unknown (Lipscomb, Hardie, and Dubielzig, 2004; Au et al., 2006). Initial treatment for primary spontaneous pneumothorax may include thoracentesis followed by tube thoracostomy; however, the long-term recurrence rate with pleural evacuation alone may be as high as 70% (Valentine et al., 1996) to 87% (Holtzinger et al., 1993). A mortality rate of 59% caused by recurrent spontaneous pneumothorax following conservative treatment also has been reported (Puerto et al., 2002). In contrast, the long-term recurrence rate for dogs with ruptured pulmonary bullae or blebs following complete or partial lung lobectomy was 12.5% in one study (Valentine et al., 1996), and the mortality rate related to surgical complications was less than 5% (Holtzinger et al., 1993). Therefore early exploratory thoracotomy following CT or thoroscopy is still recommended for diagnosis and treatment of primary spontaneous pneumothorax to optimize both survival and resolution (Puerto et al., 2002).

A median sternotomy is the standard surgical approach to adequately evaluate each hemithorax. Complete visual and tactile inspection of all lung lobes should be performed systematically. The thoracic cavity is subsequently filled with saline to identify the source(s) of air leakage from the affected lung during positive-pressure ventilation. Partial lung lobectomy may be considered if focal,

peripheral pulmonary bullae are confirmed. Complete lung lobectomy should be performed if bullous disease is located toward the hilus or involving the majority of the lung lobe parenchyma. Histopathologic examination and bacterial or fungal culture or both should be considered if clinically indicated. Mechanical (gauze sponge) or chemical (tetracycline, sterile talc) pleurodesis may be performed if diffuse bullous emphysema is observed; however, the efficacy of this form of treatment for spontaneous pneumothorax in dogs is unknown (Orton, 1993). Mechanical abrasion and chemical sclerosis (talc slurry) were evaluated for efficacy of pleurodesis in normal dogs. Complete obliteration of the pleural space was not achieved after either treatment; however mechanical abrasion may be useful as an adjunctive treatment for bullous emphysema (Jerram et al., 1999). On rare occasion pneumothorax persists despite a negative thoracic exploratory. Chemical pleurodesis with tetracycline has met with some success in controlling air leakage.

Recently thoracoscopy has also been used to successfully locate and surgically excise the lung lobes affected with primary spontaneous pneumothorax in three dogs (Brissot et al., 2003). Visualization of bilateral hemithoraces was performed, and endoscopic excision of the affected areas documented bullous emphysema. All dogs recovered without recurrent pneumothorax through 18 to 29 months after surgery. Advantages of thoracoscopic evaluation and treatment may include easier identification of pulmonary bullae and decreased postoperative pain and morbidity.

CHAPTER 155

Pulmonary Thromboembolism

SUSAN G. HACKNER, *New York, New York*

Pulmonary thromboembolism (PTE) is the obstruction of a pulmonary vessel, or vessels, by a blood clot. Blood clots can develop locally or at a distant site and translocate to the pulmonary vasculature. Thromboemboli mechanically obstruct arterial blood flow, release humoral factors, and stimulate neurogenic reflexes. Subsequent alterations in respiratory and hemodynamic function are responsible for the clinical signs and diagnostic findings in patients with PTE. The condition ranges from incidental, clinically insignificant disease to massive embolism and death.

The actual incidence of PTE in small animals is uncertain. An incidence of 0.9% in the general canine necropsy population has been reported. However, necropsy studies underestimate the incidence of PTE because not all patients with PTE die and because thrombi lyse rapidly following

death (50% dissolution within 3 hours). The incidence of PTE in critically ill animals and in patients with certain disease states is appreciable. Recognition of these conditions and their risk for thromboembolism (TE) is crucial to diagnosis and to decisions regarding prophylaxis.

PTE is extremely underdiagnosed in veterinary patients. Antemortem diagnosis is hindered by a lack of clinical awareness, clinical signs that resemble many other disease processes, and the relatively invasive or specialized tests required for definitive diagnosis. In retrospective studies PTE was suspected antemortem in less than 40% of affected dogs and 14% of affected cats.

Mortality rates of PTE in animals are unclear but are probably significant. Patient survival often depends on a prompt diagnosis and appropriate therapy instituted without delay.

ETIOLOGY

Thrombosis depends on three major risk factors: endothelial injury, blood stasis, and alterations in the blood constituents to favor thrombosis. This concept is known as Virchow's triad. Although all three factors are prothrombotic or thrombophilic, true hypercoagulability refers to a quantitative or qualitative defect in the coagulation system: platelet hyperaggregability, excessive activation or decreased removal of coagulation factors, deficiencies of natural anticoagulants (antithrombin, protein C), or defective fibrinolysis. The term *hypercoagulable states* in dogs and cats refers to acquired disorders in patients with underlying systemic disease known to be associated with an increased risk of thrombosis. In these patients the pathogenesis is generally multifactorial and complex. Inherited hypercoagulable states have not been reported in animals.

PTE has been shown to be associated with the following conditions in dogs: protein-losing nephropathy, neoplasia, cardiac disease (dirofilariasis, endocarditis, and cardiomyopathy), necrotizing pancreatitis, immune-mediated hemolytic anemia (IMHA), hypercortisolism (naturally occurring hyperadrenocorticism and corticosteroid therapy), diabetes mellitus, atherosclerosis, sepsis, trauma, and major surgical procedures. With the exception of cardiac disease, these conditions are all considered hypercoagulable states. In studies of necropsied dogs with PTE, the majority of dogs (59% and 64%) had more than one potentially hypercoagulable state. Many dogs had thrombosis in other organ systems.

PTE in cats is most commonly associated with cardiac disease (cardiomyopathy) and neoplasia. Other reported conditions include pancreatitis, IMHA, protein-losing nephropathy, protein-losing enteropathy, hypercortisolism, and sepsis. In one study 47% of cats had multiple disease processes that may have predisposed to TE.

PATHOPHYSIOLOGY

The pulmonary vascular bed filters venous blood. As a result, thromboemboli in the venous circulation become trapped in the pulmonary vasculature. In the healthy lung this vasculature has tremendous reserve capacity; minor occlusions are well tolerated. However, if occlusion is substantial or if it occurs in a patient with preexisting pulmonary or cardiac compromise, the consequences are clinically significant. Such sequelae may be pulmonary and/or hemodynamic.

Pulmonary consequences of PTE include ventilation-perfusion mismatch, bronchoconstriction, hypoxemia, and hyperventilation. Somewhat later (24 to 48 hours), two additional complications may occur (i.e., regional loss of surfactant and rarely pulmonary infarction). These result in atelectasis, edema, and effusion.

Hemodynamic consequences of PTE are related to the magnitude of the obstruction and the preexisting status of the cardiovascular and pulmonary systems. If reserve capacity is exceeded, pulmonary vascular resistance increases, resulting in increased right ventricular afterload and ventricular oxygen requirements. If these exceed supply, ischemia, arrhythmias, or right ventricular failure

ensues. Obstruction to pulmonary blood flow and the resultant decrease in venous return may lead to decreased cardiac output.

The burden caused by massive PTE is largely the result of mechanical obstruction. This is exacerbated by hypoxia-induced vasoconstriction and the release of humoral substances from activated platelets on the surface of the thrombus. PTE is a dynamic event; thrombi can undergo lysis, fragmentation, or growth. Pathophysiologic consequences reflect such changes, and findings depend on the point in time at which they are examined.

CLINICAL PRESENTATION

The severity of clinical signs reflects the magnitude of respiratory and cardiac compromise and the ability of these systems to compensate for the insult. Signs range from mild to profound compromise and death. Symptoms are variable and inconsistent and can mimic a multitude of other diseases. The most common signs are dyspnea, tachypnea, and depression. Other signs include coughing, hemoptysis, cyanosis, and hypoperfusion. Collapse, shock, and sudden death can occur in patients with markedly decreased cardiac output.

Adventitious lung sounds may be auscultable in patients with pulmonary edema, hemorrhage, or bronchoconstriction. Pleural effusion may be detectable if present. Tachycardia occurs frequently. In patients with pulmonary hypertension a loud or split second heart sound may be auscultable. Signs of hypoperfusion occur in patients with marked hemodynamic compromise.

DIAGNOSIS

The diagnosis of PTE is often very difficult. It can resemble many other conditions such as pneumonia, pulmonary edema, intrapulmonary hemorrhage, neoplasia, and pleural effusion. Findings on routine tests are generally nonspecific, and specialized techniques are required for diagnostic confirmation. These techniques are either invasive or not widely available.

The first step in the diagnosis of PTE is an index of suspicion. PTE should be on the list of differentials in any patient with an acute onset of respiratory signs, particularly if the patient has no prior evidence of respiratory disease. The presence of predisposing diseases or potential hypercoagulable states increases the degree of suspicion.

Initial assessment of the patient involves thoracic radiography, arterial blood gas analysis, and routine hematologic and biochemical screening. If these are consistent with PTE or if they fail to identify another diagnosis, secondary assessment is indicated. Secondary assessment should include cardiac evaluation via echocardiography, determination of D-dimer concentrations, screening for possible underlying thrombophilic conditions, and testing for hypercoagulability (when possible). If results of these tests support a possible diagnosis of PTE, confirmatory tests should be considered. When confirmatory tests are not available or feasible, the diagnosis of PTE must be based on clinical likelihood determined from the aforementioned assessments and on elimination of other potential etiologies.

Initial Assessment

Thoracic Radiography

Most patients with PTE have abnormal thoracic radiographs, but findings are nonspecific. Two common radiographic patterns are described: regional oligemia (hypovascular lung regions) and pulmonary infiltration. Regional oligemia appears as areas of increased radiolucency and represents reduced vascular filling distal to the thrombotic occlusion. Oligemia is best identified on ventrodorsal and dorsoventral radiographic views. Pulmonary infiltrates represent areas of hemorrhage, atelectasis, or infarction. They are most commonly alveolar but may be interstitial or mixed alveolar-interstitial. They can be solitary or multiple and may involve more than one lung lobe. They are usually amorphous with indistinct borders. Less commonly radioopacity involves an entire lobe creating distinct lobar borders. Infiltrates are more common in the right and caudal lobes. Infrequently infiltrates appear as distinct, wedge-shaped densities with the apex toward the pulmonary hilus.

Pulmonary vessel changes may be evident, including enlargement of the main pulmonary artery segment and attenuation of a lobar artery or vein. Cardiomegaly may also occur. Pleural effusion is not common in dogs and is usually mild. It appears to be more common in cats.

Patients with PTE can have normal thoracic radiographs. In canine studies the percentage of dogs with normal radiographs ranged from 9% to 27%. In a feline study 7% had normal thoracic radiographs. Since these are necropsy studies and thus select for more severely affected patients, the occurrence of normal radiographs in animals with PTE is likely even higher. Thoracic radiographs that underestimate the degree of clinical respiratory compromise are an important clue to the presence of PTE.

Arterial Blood Gas Analysis

Arterial blood gas analysis can aid in the diagnosis of PTE and is relevant to the management thereof, but changes are not pathognomonic. The most common abnormalities are (in descending order): an increased alveolar-arterial oxygen tension gradient ($P_{(A-a)O_2}$), hypoxemia, hypocapnia, and decreased oxygen responsiveness. Hypercapnia is uncommon but can occur with severe compromise. When these changes are present, they are nonspecific indicators of inefficient gaseous exchange and do not confirm a diagnosis of PTE. Moreover, the presence of normal blood gas values does not exclude PTE.

Routine Hematologic and Biochemical Studies

These have limited value in the diagnosis of PTE. When abnormal results are present, they generally reflect inflammation, hypoxemia, or stress. However, results may be useful in identifying predisposing hypercoagulable states.

Secondary Assessment

Echocardiography

Echocardiography can be a valuable tool in the assessment of patients with suspected PTE. It may show changes consistent with PTE or evidence of compromise that impacts management decisions.

Rarely echocardiography demonstrates a right-sided thrombus ("thrombus in transit"), tricuspid valve throm-

bus, or organized thrombus in the main pulmonary artery. More commonly it demonstrates changes suggestive of PTE and pulmonary hypertension. These include dilation of the right ventricle, pulmonary artery, or inferior vena cava; right ventricular hypokinesis; tricuspid regurgitation; or abnormal septal wall motion. However, a normal echocardiogram does not exclude a diagnosis of PTE; a significant percentage of patients with PTE evidence no echocardiographic anomalies.

Right ventricular hypokinesis is associated with a doubling of the mortality rate in humans. Therefore its presence prompts a more aggressive approach to therapy. Arterial blood pressure is not a reliable indicator because hypokinesis can be present in normotensive patients.

D-Dimers

Of the laboratory markers, only D-dimers have proven clinical usefulness in the diagnosis of PTE in humans. D-dimer is a unique fibrin degradation product that is formed when cross-linked fibrin is proteolyzed by plasmin. Therefore it is specific for active coagulation and fibrinolysis and useful for detecting TE. However, the half-life of D-dimers is short (approximately 5 hours). As such they are only useful for detection of acute TE. D-dimers are not specific for TE. Elevated D-dimers have been demonstrated in dogs with neoplasia, hepatic disease, renal failure, cardiac failure, internal hemorrhage, disseminated intravascular coagulation, and following surgical procedures.

D-dimers in humans have a high negative predictive value for PTE and are used extensively as a screening test. Most workers recommend their use as part of a diagnostic algorithm to determine which patients require more definitive testing. They are considered most useful to rule out PTE in patients deemed to have a low clinical probability.

The use of D-dimers in small animal patients with suspected PTE is less clear but appears similar. Sensitivities of 89% to 100% have been reported in dogs, using the standard enzyme-linked immunosorbent assay test, a latex bead agglutination test (Accuclot D-dimer, Sigma), and a canine-specific point-of-care test (AGEN canine D-dimer test, Sigma). Reported specificity is approximately 70%. When semiquantitative methods have been used, specificity approaches 90%, with strong positive results (greater than 1000 ng/dl on latex agglutination) occurring only in patients with TE and with hemoabdomen.

Based on the available data in dogs, it appears that PTE can be considered extremely unlikely if the D-dimer test is negative and clinical suspicion is low. However, PTE is not excluded by a negative D-dimer, especially if the time period from event to presentation is prolonged. A positive test should always be interpreted in the light of other clinical findings. If these support PTE, further testing is indicated. A strong positive test in the absence of intracavitary hemorrhage is highly suggestive of TE.

Screening for Underlying Conditions

Since PTE occurs almost exclusively secondary to one or more underlying conditions, any suspicion of PTE should prompt a thorough investigation for these conditions. Although their presence does not confirm PTE, they provide further support when definitive diagnosis is not possible, and they are essential in clinical management.

Testing for Hypercoagulability

The presence of hypercoagulability neither confirms nor predicts TE. It merely indicates that TE is possible and, together with other compatible findings, enables the clinician to build a stronger case for a diagnosis. However, laboratory confirmation of hypercoagulability is difficult.

The use of thromboelastography (TEG) has been described in small animals for the assessment of overall hypercoagulability. Clinical experience is encouraging. However, few institutions offer TEG, and further studies are needed to fully elucidate clinical usefulness.

Significant hyperfibrinogenemia can indicate potential hypercoagulability but occurs in few of the hypercoagulable states (e.g., some cases of pancreatitis and sepsis). The majority of patients with PTE do not have hyperfibrinogenemia. Similarly, assay of antithrombin (AT-III) concentration or activity may be useful in some cases. A correlation with thrombotic risk has been shown when AT-III deficiency is the primary mechanism for thrombosis (e.g., protein-losing nephropathy). AT-III levels may also be decreased as a result of massive TE. Normal AT-III levels do not exclude hypercoagulability.

The routine coagulogram is not helpful in identifying hypercoagulation or TE. It is frequently normal. If abnormalities are present, they are nonspecific and generally reflect a consumptive process. There is no known correlation between thrombocytosis or shortened coagulation times and thrombosis.

Confirmation of Pulmonary Thromboembolism

Pulmonary scintigraphy has been shown to be sensitive and specific for experimental PTE and has been used successfully clinically in dogs and cats. The technique, however, is limited to few referral facilities with scanning equipment. The rationale of pulmonary scintigraphy is that occlusion of pulmonary vessels by a thrombus results in areas of the lung that continue to be ventilated despite the absence of perfusion. Radioactive labeling of the pulmonary blood (perfusion scan) followed by the inspired air (ventilation scan) allows demonstration of areas of the lungs with ventilation-perfusion mismatch. A normal perfusion scan virtually excludes a diagnosis of PTE, but an abnormal perfusion scan is not specific for PTE; perfusion defects can result from numerous nonthrombotic conditions, including pneumonia, edema, contusions, obstructive pulmonary disease, and atelectasis. However, these conditions are associated with decreased regional ventilation and an abnormal ventilation scan.

Spiral computed tomographic angiography (CTA) is used extensively for the diagnosis of PTE in humans. The technique allows precise visualization of the pulmonary vasculature and is rapid and noninvasive, making it an ideal modality in the unstable patient. Reported sensitivity in humans is as high as 95.5%, with a specificity of 97.6%. The technique has not yet been reported in small animals, but clinical experience at several institutions is encouraging.

Selective pulmonary angiography remains the gold standard for the diagnosis of PTE. It is indicated for the definitive diagnosis or exclusion of PTE when scintigra-

phy or spiral CT is unavailable or inconclusive. Iodinated contrast medium is rapidly injected via a large-bore catheter into the pulmonary arterial tree. The pulmonary arterial system can then be visualized via radiography. Intraluminal filling defects, abrupt termination of pulmonary arteries, and the complete absence of arterial branches are diagnostic for PTE. A regional loss of vascularity, asymmetric blood flow, tortuous pulmonary arteries, and abrupt tapering of peripheral vessels support a diagnosis of PTE but are nonspecific. A negative selective arteriogram essentially excludes clinically significant PTE. Because the procedure requires general anesthesia, which depresses cardiovascular function and is invasive, it constitutes a significant risk in the compromised patient. This limits the use of this technique in clinical veterinary practice.

Nonselective pulmonary angiography is easier and safer than selective techniques. General anesthesia and specialized equipment typically are not required. Contrast medium is injected via a large-bore catheter into the right side of the heart or the jugular vein. This study is less sensitive and more difficult to interpret than selective angiography because of dilution of the contrast medium by venous blood and the superimposition of vascular structures.

THERAPY

Therapy of PTE should begin as soon as possible. It should include support of the respiratory and cardiovascular systems, prevention of thrombus propagation and recurrence, and possibly thrombolysis. It appears that a relatively small percentage of PTE events are immediately fatal. In the normal dog thrombi begin to lyse spontaneously within hours. Even in patients with disturbed fibrinolysis, some degree of reorganization and lysis occurs in the days following the thromboembolic event. Therefore, if the patient can be supported through the respiratory and cardiovascular compromise and further exacerbations can be prevented, survival is possible. In some cases compromise may be so extreme that adequate support is not possible and survival unlikely. In such cases pharmacologic thrombolysis may be indicated.

Respiratory and Cardiovascular Support

Oxygen supplementation is indicated when dyspnea is evident and/or when partial pressure of arterial oxygen decreases below 70 mm Hg or arterial O₂ saturation to less than 92%. In addition to relieving hypoxemia, oxygen supplementation has been shown to dilate pulmonary vessels, improve hemodynamics, reduce pulmonary hypertension, and improve right ventricular function. Theoretically bronchodilators may be beneficial. Methylxanthine bronchodilators such as theophylline have small positive inotropic effects and produce sustained pulmonary vasodilation. Theophylline improves diaphragmatic contractility in dogs and reduces respiratory muscle fatigue. These effects may be beneficial in extremely dyspneic or tachypneic patients in which muscle fatigue can result in respiratory failure.

Perfusion should be optimized in any patient with hypoxemia. In these patients arterial oxygen content is deficient, and any decrease in perfusion further exacerbates the already reduced tissue oxygen delivery. In addition, optimizing perfusion reverses the prothrombotic effects of vascular stasis and hypoxia-induced endothelial injury.

Prevention of Propagation and Recurrence of Thrombi

Thrombi tend to propagate, especially in the thrombophilic and hypofibrinolytic patient, and this can result in further compromise. The patient with PTE has proved that it is thrombophilic and therefore at risk for additional thromboembolic episodes. When death occurs beyond the first few hours following PTE, it is likely caused by a recurrent embolic event. Therefore management should be focused on preventing such occurrences. Anticoagulants form the cornerstone of such management.

Anticoagulants

In general, anticoagulants do not lyse existing thrombi; they are indicated to inhibit propagation and prevent recurrent venous thrombosis. Since PTE is primarily a venous event, anticoagulants are indicated in all cases of PTE.

Unfractionated heparin. Heparin is the standard of care in humans with PTE. Until further data are available on alternate anticoagulants in small animal patients, unfractionated heparin remains the drug of choice for initial PTE therapy.

Unfractionated heparin is composed of mucopolysaccharides of varying molecular weights. The primary mechanism of action is the potentiation of AT-III activity, leading to the inactivation of thrombin (factor IIa), and factors Xa, IXa, XIa, and XIIa. Of these, thrombin and factor Xa are the most responsive to inhibition. The relative effect of heparin on these factors depends on its molecular size. Smaller heparin molecules (less than 18 saccharide units) are unable to catalyze thrombin inhibition. However, these molecules are effective in catalyzing the inhibition of factor Xa. Other effects of heparin include reduced blood viscosity, decreased platelet function, increased vascular permeability, and mildly enhanced fibrinolysis. These effects contribute to the hemorrhagic risk.

The anticoagulant effects of a standard dose of heparin vary widely among patients. Heparin may be poorly absorbed from subcutaneous sites. The plasma clearance of heparin depends on a rapid, dose-related, saturable cellular mechanism and a slower, nondose-related renal clearance. As such, the intensity and duration of effect increase disproportionately with increasing dose. Higher-molecular weight species are cleared more rapidly than lower-molecular-weight species, resulting in varied anticoagulant activity over time. Binding of heparin to plasma proteins, endothelial cells, and platelets contributes to the unpredictable response. In addition, some patients appear to have heparin resistance, requiring larger doses to achieve a therapeutic effect.

It has been shown in humans that, unless a prescriptive nomogram is used, many patients receive inadequate heparinization in the initial 24 to 48 hours of therapy, resulting in an increased incidence of recurrent TE. Successful heparin therapy necessitates monitoring the anticoagulant response and titrating the dose to the individual patient. Anticoagulant response can be monitored via the plasma heparin concentration or the partial thromboplastin time (PTT). The therapeutic range of heparin is a concentration of 0.3 to 0.7 units/ml by antifactor Xa assay, and 0.2 to 0.4 units/ml by protamine sulfate titration. However, the turnaround time for these assays makes them impractical for clinical monitoring of the PTE patient. In humans therapeutic heparin concentrations are achieved with a dose of heparin that prolongs the PTT to approximately 1.5 to 2.5 times that of controls. This range is also quoted in the veterinary literature. However, observations in canine studies suggest that this may be excessive (Mischke and Jacobs, 2001). When heparin doses were given to dogs to prolong the PTT to twice normal, plasma heparin concentrations were above therapeutic range. Until further data are available, the author uses a target PTT range of 1.5 to 2 × baseline. A limitation in the use of the PTT to guide heparin therapy is that it is not directly correlated with anticoagulant activity and clinical efficacy. This is largely because the PTT effect of heparin reflects primarily its antifactor IIa activity.

Heparinization guidelines for humans are established. However, it is impossible to give evidence-based recommendations in small animals. There are exceedingly few studies, and most quoted doses are anecdotal. Therefore it would appear prudent to use protocols established in humans and in animal models and to closely monitor PTT values and/or heparin concentrations. For humans the Consensus Conference on Antithrombotic Therapy recommends an intravenous bolus of heparin, followed by continuous-rate infusion (Hyers et al., 2001). Studies have demonstrated no increase in major bleeding compared to subcutaneous administration. The author uses an extrapolation of this protocol in dogs (Table 155-1). Because AT-III is required for heparin effect, plasma transfusion is recommended in patients with documented or suspected AT-III deficiency.

Subcutaneous administration of heparin is not recommended for acute PTE therapy. Although this protocol can reach target PTT ranges, they are rarely achieved rapidly. The use of subcutaneous heparin in patients with acute PTE should be reserved for patients in which intravenous heparin is not feasible. Published doses vary enormously. A small number of canine studies have shown marked individual variability in response, emphasizing the importance of monitoring. The author uses a dose of 200 units/kg every 6 hours, with adjustments based on regular PTT determinations. There is evidence that PTT results do not correlate reliably with plasma heparin concentrations in cats. For this reason heparin infusions are difficult in cats and alternative anticoagulation may be preferable.

Low-molecular weight heparin. Low-molecular weight heparins (LMWHs) are manufactured from unfractionated heparin to yield smaller molecules. These differ in several important respects: superior subcutaneous bioavailability; a prolonged half-life and predictable renal clearance, enabling once or twice daily dosing in humans; and predictable antithrombotic responses, permitting treatment

Table 155-1

Weight-Based Nomogram for the Intravenous Infusion of Heparin* in Dogs

PTT	Dose Change (units/kg/hour)	Additional Action	Next PTT
<1.2 × mean normal	+4	Rebolus with 80 units/kg	6 hours
1.2–1.5 × mean normal	+2	Rebolus with 40 units/kg	6 hours
1.5–2 × mean normal	0	0	6 hours for first 24 hours, then daily
2–3 × mean normal	–2	0	6 hours
>3 × mean normal	–3	Stop infusion 1 hour	6 hours

*An intravenous bolus administration of heparin of 80 to 100 units/kg is administered, followed by a continuous rate infusion of 18 units/kg/hour. A PTT is evaluated 6 hours after initiation of therapy. Adjustments are as indicated in the table.

PTT, Partial thromboplastin time.

based on body weight without laboratory monitoring. Other advantages are their ability to inhibit platelet-bound factor Xa and their decreased effect on platelet function and vascular permeability. These characteristics possibly account for fewer hemorrhagic effects at comparable anti-thrombotic dosages. Onset of action is rapid, with peak effects generally seen at 2 to 4 hours. Small-molecular weight fractions have little anti-IIa activity and cannot be monitored via PTT. Anticoagulant efficacy is monitored via an antifactor Xa assay. In humans favorable dose-response characteristics make monitoring unnecessary in most patients except those with renal failure.

In human clinical trials subcutaneous LMWH has shown similar or superior efficacy when compared with intravenous unfractionated heparin with regard to recurrent PTE and mortality. Although these drugs are considerably more expensive, the reduced risk and decreased need for monitoring contribute to cost-effectiveness.

Experience with LMWH in small animals is limited. Dalteparin (Fragmin, Pharmacia) at a dose of 150 units/kg every 8 hours subcutaneously was shown to achieve therapeutic ranges in five healthy dogs (Mischke et al., 2001). A study of pharmacokinetics of dalteparin in normal cats suggested that a dose of 100 units/kg every 24 hours subcutaneously was effective. However, clinical experience with this drug in cats indicates that every 6- to 8-hour dosing may be necessary for sustained therapeutic effects. Enoxaparin (Lovenox, Aventis) has also been used in small animals, but published reports are lacking. Until more information is available on effective dosing in small animals, it is hard to recommend LMWH as first choice in the initial therapy of PTE. However, it can be considered when intravenous heparin infusion is not feasible. In this role LMWH is likely preferable to intermittent subcutaneous unfractionated heparin.

Based on current knowledge and personal experience, the author recommends a starting dose of dalteparin of 150 units/kg every 8 to 12 hours in the dog and 100 units/kg every 8 hours in the cat. A reasonable starting dose of enoxaparin is 1 mg/kg every 12 hours. Regardless, it is imperative that anticoagulant efficacy be monitored via anti-Xa assay until an effective dose is established for that patient. Therapeutic range extrapolated from human subjects is an antifactor Xa of 0.3 to 0.7 units/ml. Samples should be collected 24 hours after initiation of therapy, just before injection, and 2 to 4 hours after injection to determine peak effect and duration. Dose and frequency are adjusted accordingly. Once an effective protocol is established for the patient, continued monitoring appears unnecessary, except for patients in renal failure.

Antiplatelet Drugs

Antiplatelet drugs should be considered together with but not in lieu of anticoagulant therapy. Antiplatelet drugs inhibit platelet aggregation, thereby preventing the formation of the primary platelet plug. Traditionally these drugs have been used for the prevention of arterial thrombosis (e.g., aortic, cerebrovascular) since arterial thrombi have a large platelet component compared to venous thrombi. However, there is compelling evidence to suggest a role for antiplatelet drugs as adjunctive therapy in PTE. Recent experimental studies of PTE in the presence of radio-labeled platelets have shown that platelets accumulate in venous thrombi in the early stages. As the thrombus ages, platelet acquisition slows, and the proportion of platelets decreases. Furthermore, venous thrombi activate platelets, causing release of serotonin, adenosine diphosphate (ADP), and thromboxane A_2 (Tx A_2). Physiologic consequences include bronchoconstriction, vasoconstriction, and pulmonary hypertension. Antiplatelet drugs may ameliorate these effects. Finally, there is convincing clinical evidence in humans, with trials demonstrating a decrease in the incidence of PTE by over one third when antiplatelet therapy was included in the protocol.

Aspirin is the only antiplatelet drug that has been widely used in veterinary patients. It is a cyclooxygenase (COX) inhibitor, thus preventing the formation of various prostanoids, including thromboxane A_2 (TXA $_2$) and prostacyclin (PGI $_2$). TXA $_2$ is produced by platelets, is largely a COX-1-derived product, and induces platelet aggregation. The antiplatelet effect of aspirin is irreversible, rapid, and saturable. Prostacyclin, produced by vascular endothelial cells is derived from both COX-1 and COX-2, and inhibits platelet aggregation. Aspirin is approximately fifty-fold more potent in inhibiting COX-1 than COX-2. Thus, intuitively, antiplatelet therapy with aspirin should require an ultra-low dose that inhibits TXA $_2$ production while sparing prostacyclin. Indeed, early veterinary studies in small numbers of dogs supported this hypothesis. More recent, large, human clinical trials demonstrate that aspirin is effective over a wide range of doses, including high doses, but that the adverse gastrointestinal effects of the drug are dose related.

The optimal antiplatelet dose of aspirin in dogs is not entirely established. Studies in healthy dogs, and in dogs with IMHA, indicate that a dose of 0.5 mg/kg q24hr may result in effective platelet inhibition. In cats, a dose of

81 mg/cat q3 days traditionally has been used. A retrospective study of aortic thromboembolism in cats revealed no statistical difference in outcome between traditional and low-dose (5 mg/cat q3 days) aspirin, but significantly fewer adverse effects with the low-dose protocol.

The thienopyridines (clopidogrel, ticlopidine) selectively inhibit ADP-induced platelet aggregation, and have no effect on cyclooxygenase (suggesting a synergistic effect with aspirin). Onset of action is not immediate; platelet inhibition occurs by 2 days, and reaches a steady state after 5 to 7 days. As with aspirin, the defect in platelet function persists for the life of the platelet.

Clopidogrel has largely superseded ticlopidine in human medicine due to superior potency, more rapid onset, and a lower incidence of adverse effects. Several large trials in human patients have demonstrated a marginal risk reduction of vascular events with clopidogrel compared with aspirin, with similar rates of gastrointestinal bleeding. Current recommendations are in most instances for aspirin therapy. Clopidogrel is reserved for patients who have an aspirin contraindication, have failed aspirin therapy, or who have a >20% risk of a vascular event.

Veterinary experience with these drugs is limited. Ticlopidine (62 mg/kg q24hr) has been shown to effectively inhibit ADP-induced platelet aggregation in healthy dogs. In heartworm-infected dogs, the dose required for this effect was greater and variable. A study in normal cats showed that, at ticlopidine doses sufficient to consistently inhibit platelet aggregability, cats became anorectic. A similar study of clopidogrel suggests that doses ranging from 18.75 to 75 mg q24hr are well-tolerated and result in significant inhibition of platelet aggregation. Dosages at 18.75 mg to 37.5 mg per day of clopidogrel are often used long-term in cats with cardiomyopathy and appear to be well tolerated.

Thrombolysis

Thrombolytic agents are plasminogen activators that result in the production of plasmin and subsequent dissolution of the fibrin thrombus. Advantages of thrombolytic therapy include rapid clot lysis, improved pulmonary perfusion, accelerated reversal of right heart failure, and improved hemodynamic stability. These must be weighed against the risk of massive hemorrhage, which is appreciable. The goal of thrombolytic therapy is to rapidly restore circulation so that the procedure is clinically beneficial and the risks of therapy justifiable.

Thrombolytic therapy is reserved for patients with life-threatening PTE that are unlikely to survive without rapid reperfusion. Contraindications include active internal bleeding, hypertension, recent (within 2 to 3 weeks) surgery or organ biopsy, and gastrointestinal ulceration.

To facilitate decisions regarding the use of thrombolytic therapy, humans with PTE are categorized according to hemodynamic stability and right ventricular function. Thrombolytic therapy reduces mortality in patients with massive PTE and shock. In hemodynamically stable patients pharmacologic thrombolysis has not been found to improve outcome, with the exception of patients with evidence of right ventricular dysfunction. This latter patient subset has a high mortality rate with anticoagulation alone, and

studies have shown that timely intervention with thrombolytic therapy increases survival. Anticoagulant therapy, with intravenous unfractionated heparin or subcutaneous LMWH, is recommended following thrombolysis.

Veterinary experience with thrombolytic agents is limited, making evidence-based recommendations for their use impossible. Risk-to-benefit ratios have not been investigated. As in humans, thrombolytic therapy may be indicated when PTE is accompanied by hemodynamic instability or right ventricular hypokinesis. However, we have yet to determine safe and effective protocols. Thrombolytic agents have been investigated in experimental canine PTE, but there are no published reports in clinical cases. There are a small number of reports involving the use of thrombolytics in animals with nonpulmonary TE.

The successful use of streptokinase (SK) has been described in four dogs with nonpulmonary TE. Protocols varied tremendously. Loading doses of 5,200 to 18,000 units/kg were administered over 30 minutes once or three times. Maintenance dosages ranged from 2083 to 9000 units/kg/hour, infused for 3 to 10 hours per day. The use of SK has been reported in cats with aortic TE, using a loading dose of 90,000 units over 20 to 30 minutes, followed by a maintenance dosage of 45,000 units/kg/hour for 3 or more hours. Most cats had evidence of thrombus dissolution, but bleeding complications were common, and mortality high.

Tissue plasminogen activator (t-PA) has a high affinity for fibrin, preferentially activating thrombus-associated plasminogen. Theoretically this decreases the risk of hemorrhage. In humans t-PA has shown higher success rates compared with SK and fewer adverse effects and is more effective in the lysis of aged thrombi. The successful use of t-PA has been described in a dog with aortic thrombosis. Bolus injections of 1 mg/kg every 60 minutes for a total of 10 doses resulted in resolution. Experience with t-PA in cats with aortic TE has not been encouraging. Treatment was successful in 43% of cats, but 50% died during therapy, most deaths resulting from reperfusion. The author has used t-PA (together with heparin) with some success in a small number of dogs with PTE. Bolus injections of 1 mg/kg are given over 15 to 20 minutes every 60 to 180 minutes until evidence of improvement and then repeated thereafter as needed. No major hemorrhage has been noted; minor hemorrhage has prompted only temporary discontinuation of the drug. Studies in humans indicate that a single infusion of t-PA over 2 hours may be superior to intermittent bolus injections. This remains to be evaluated in animals.

Ongoing Therapy

Initial therapy should be continued until the patient is stabilized and respiratory status is steadily improving. At that point the patient can be transitioned to ongoing therapy in preparation for hospital discharge. Ongoing therapy is aimed at preventing recurrent TE and is addressed in the section on Pharmacologic Prophylaxis later in the chapter. Therapy should be continued until the risk of TE is considered sufficiently decreased, but this is difficult to determine objectively. In patients with short-term reversible causes such as pancreatitis, I continue therapy for 1 to 2 weeks following clinical recovery. In patients

with longer-term ongoing risk such as IMHA, anticoagulant therapy is continued until corticosteroids are weaned. Indefinite therapy is recommended in patients with recurrent TE, TE complicating malignancy, or cardiac disease.

PREVENTION

The mortality rate of PTE is substantial, with some deaths occurring rapidly before the diagnosis can be confirmed and effective treatment implemented. Moreover, diagnosis is difficult, and treatment of established PTE is not universally successful. This makes prevention imperative in the patient at risk for PTE. Prevention should address all aspects of Virchow's triad. This includes: (1) minimizing vascular stasis by maintaining adequate perfusion; (2) minimizing vascular injury by the appropriate handling of venous catheters; and (3) altering the hemostatic system via the appropriate use of drugs. Drugs are indicated when there is significant risk for PTE.

Objective determination of PTE risk in veterinary patients is difficult. The incidence of PTE in specific diseases is largely unknown, and few laboratory tools are available to confirm hypercoagulability. Assessment of risk remains largely subjective. Understanding the risk factors in patient groups and in individual patients forms the basis for such assessment.

Undoubtedly the single most convincing evidence of risk is a prior PTE episode. Prophylactic drugs are indicated until the cause is reversed. In many patients multiple risk factors are present, and the risks are cumulative (i.e., a thrombophilic patient may not develop PTE until precipitated by another hypercoagulable state or thrombophilic condition such as catheterization, surgery, hypoperfusion, or glucocorticoid therapy). Such a situation should prompt consideration of anticoagulant therapy. The author considers severe IMHA, severe acute pancreatitis, and sepsis to be indications for anticoagulant therapy. However, risk stratification is subjective and based on the severity of disease and concomitant risk factors. Nephrotic syndrome is a significant risk for PTE. Determination of AT-III level might assist in risk assessment. Risk may also be estimated by the severity of renal protein loss, the existence of potentially contributing factors, and any history of prior TE events.

Patients with hyperadrenocorticism or diabetes mellitus appear to have a low incidence of TE, and the need for prophylactic drugs in these patients is doubtful. Risk increases when another thrombophilic condition is applied. In humans with hyperadrenocorticism, TE risk is correlated with systemic hypertension. It is the author's opinion that this is true in dogs. Although anticoagulants are not generally indicated in the dog with uncomplicated Cushing's disease, the patient that is to undergo adrenalectomy, that has hypertension or protein-losing nephropathy, or that has had a prior TE episode is a candidate for anticoagulation.

Pharmacologic Prophylaxis

The choice of anticoagulant for PTE prophylaxis depends on the anticipated duration and the compliance and finances of the owner. Options include subcutaneous heparin, warfarin, and LMWH.

Prophylaxis is traditionally initiated with low-dose, subcutaneous, unfractionated heparin. Small fixed doses are used in humans. This protocol does not require laboratory monitoring and has been shown to reduce the rate of fatal PTE by two thirds. Recommended doses of heparin for prophylaxis in small animals range from 100 to 200 units/kg every 8 to 12 hours subcutaneously. These doses do not appear to result in major hemorrhage, but efficacy rates have yet to be assessed. Gradual weaning of heparin has been recommended in the veterinary literature, although there is little evidence to support this practice.

Warfarin is most commonly used for long-term outpatient TE prophylaxis. It is an oral vitamin K antagonist, thus inhibiting the activation of vitamin K-dependent factors. Because of the half-lives of these factors, the anticoagulant effect of warfarin is not immediate. During the first 24 to 48 hours of therapy, only factor VII and protein C are significantly affected. Inhibition of protein C is prothrombotic, thus potentially leading to thrombosis during initial therapy before other factors are inhibited. For these reasons heparin therapy should always overlap warfarin for at least the first 2 days and until therapeutic levels of warfarin are achieved. Warfarin is initiated at a dose of 0.05 to 0.1 mg/kg every 24 hours orally in the dog and the cat. A therapeutic range is generally achieved within 5 to 7 days. Therapy is monitored by use of the prothrombin time and the calculated International Normalization Ratio (INR) (Kirk and Bonagura, 1995). The therapeutic range for warfarin is an INR of 2.0 to 3.0. The INR should be assessed daily until a therapeutic range is achieved; heparin is then discontinued. Because of the risk of hemorrhage and the influence of diet, comorbidity, and various drugs, close continued monitoring of warfarin therapy on an outpatient basis is essential.

LMWHs are an attractive alternative to warfarin. They are less associated with hemorrhage and, after the initial establishment of an effective dose, do not require ongoing monitoring. Since onset of action is rapid, unfractionated heparin can be discontinued when LMWH is initiated. These benefits contribute to offsetting the costs of these drugs. However, until effective dosing protocols are established in small animals, initial dose adjustments based on anti-Xa assay are mandatory (see previous paragraphs).

Antiplatelet drugs are indicated as adjunctive therapy for TE prophylaxis. Together with the aforementioned rationales for the use of these drugs, most of the thrombophilic conditions in animals can result in both venous and arterial thrombosis. Therefore the addition of an antiplatelet drug has merit. In a recent study of dogs with IMHA, patients that received ultralow dose aspirin (with or without heparin) had improved outcomes without adverse gastrointestinal effects.

CHAPTER 156

Pulmonary Hypertension

ROSEMARY A. HENIK, *Madison, Wisconsin*

The recognition of pulmonary hypertension (PH) in dogs and cats has become more common with the widespread use of Doppler echocardiography in small animal practice. In addition, the development of drugs that both selectively lower pulmonary artery (PA) pressures and can be given orally lends an additional reason to identify and treat PH in cats and dogs. This chapter reviews the clinical classification of PH, its diagnosis, and treatment recommendations.

DEFINITION

Normal PA pressures in small animals, measured by cardiac catheterization under pentobarbital anesthesia, are 25 ± 5 mm Hg systolic, 10 ± 3 mm Hg diastolic, and mean of 15 ± 5 mm Hg. Similarly, mean PA pressure in 97 instrumented, nonsedated dogs was 14 ± 3.2 mm Hg, with a 95% confidence interval of 13.4 to 14.7 mm Hg (Haskins et al., 2005). PH is a sustained increase in the PA systolic, mean, or diastolic pressure. Based on these normal results, dogs and cats residing at sea level with a systolic PA pressure greater than 30 mm Hg, mean pressure greater than 20 mm Hg, or diastolic PA pressure greater than 15 mm Hg can be considered to have PH. Systolic PH is diagnosed most frequently in animals because of ease in estimating systolic PA pressure during Doppler echocardiography.

CLASSIFICATION AND ETIOLOGY

PH was previously classified into two categories: primary or secondary, depending on the absence or presence of identifiable causes. Primary PH, a diagnosis of exclusion,

has no known etiology and is rare, only recently documented in a dog (Glaus et al., 2004). Secondary PH develops as a result of impedance of pulmonary venous drainage (usually secondary to increased left atrial pressure), pulmonary overcirculation, or increased pulmonary vascular resistance.

PH in humans was reclassified by the World Health Organization in 1998 into five clinical categories based on shared pathophysiologic mechanisms, clinical presentation, and therapeutic options (Rich et al., 1998). The Evian Classification, named for the meeting site in France, was reviewed and modified in 2003 to ensure that it was accepted by experts in the field and was providing new information about disease mechanism and treatment efficacy. Minor modifications to the classification scheme were made based on recent published information (Simonneau et al., 2004). In addition, both the U.S. Food and Drug Administration and the European Agency for Drug Evaluation have used this clinical classification for labeling the newly approved drugs bosentan, treprostinil, and iloprost.

Although many of the diseases contributing to PH in companion animals differ from those in humans, it seems reasonable to adopt a clinical classification scheme (Box 156-1) to better define prognosis and therapeutic approach. This is especially important given that veterinarians are relatively new to identifying and addressing PH in companion animals and an organized approach to classification and treatment allows a more critical assessment of outcome.

The first category, termed *pulmonary arterial hypertension (PAH)*, includes a subgroup without identifiable cause, termed *idiopathic PAH (IPAH)*, the term *primary PH*

Box 156-1

Clinical Classification of Pulmonary Hypertension in Veterinary Patients***I. Pulmonary Arterial Hypertension (PAH)**Idiopathic pulmonary hypertension (IPAH)[†]Familial pulmonary hypertension (FPAH)[†]

Associated with PAH:

Heartworm disease

Congenital systemic-to-pulmonary shunts

Collagen vascular disease[†]Drugs/toxins[†]Persistent pulmonary hypertension of the newborn[†]**II. Pulmonary Hypertension With Left Heart Disease**

Left-sided myocardial heart disease

Left-sided valvular heart disease

III. Pulmonary Hypertension Associated With Lung Diseases and/or Hypoxemia

Chronic obstructive pulmonary disease

Interstitial lung disease

Sleep-disordered breathing[†]

Alveolar hypoventilation disorders

Chronic exposure to high altitude

Developmental abnormalities[†]**IV. Pulmonary Hypertension Caused by Chronic Thrombotic or Embolic Disease**

Thromboembolic obstruction of proximal or distal pulmonary arteries

Nonthrombotic pulmonary embolism

Heartworm disease or other parasites

Neoplasia

Foreign material (i.e., catheter or coil)

V. Miscellaneous

Compression of the pulmonary vessels

Lymphadenopathy

Neoplasia

Fibrosing mediastinitis

Granulomatous disease

Other: sarcoidosis, histiocytosis X, lymphangiomatosis[†]

*Adapted for veterinary patients from Rich S et al., 1998 and Simonneau G, 2004.

[†]Questionable significance in veterinary patients at this time.

being discarded (Simonneau et al., 2004). PAH is both a vasoproliferative and a vasoconstrictive disorder. The pathogenesis of PAH involves an imbalance between endothelium-derived relaxing factors (e.g., nitric oxide and prostacyclin) and endothelium-derived constricting factors (e.g., endothelin-1, thromboxane, serotonin), which results in increased vasomotor tone, endothelial smooth muscle cell proliferation, vascular remodeling, and thrombosis (Sharma, 2003). Familial PAH (FPAH) is also included in this category but has not been documented in veterinary patients. Reports of related animals with lesions of PAH have all had underlying congenital heart disease.

A third subgroup includes a number of conditions or diseases associated with PAH that have in common the localization of lesions to the small pulmonary muscular arteries and arterioles (i.e., the precapillary segments of the pulmonary vasculature). The mechanisms responsible for the precapillary localization of the pulmonary vascular lesions are unknown, but the conditions share similar morphologic features and respond to pulmonary arterial vasodilators. Patients with PH caused by congenital systemic-to-pulmonary shunts, collagen vascular disease, or exposure to certain drugs or toxins are included in this category. Heartworm disease, besides fitting into the thromboembolic category, can also cause PH because of inflammatory changes in the pulmonary arterial endothelial lining.

Pulmonary vascular histopathologic changes that accompany congenital heart disease are usually indistinguishable from those of IPAH; the lesions include medial hypertrophy, intimal proliferation fibrosis, and in more severe PH plexiform lesions and necrotizing arteritis. The pulmonary vascular involvement from congenital heart disease in children usually follows a period in which pulmonary resistance is low and pulmonary blood flow is high. In these patients it is suspected that shear stress caused by high flow damages endothelial cells and produces PH (Simonneau et al., 2004). Large-diameter defects are also reported in many dogs with patent ductus arteriosus and PH; however, the retention of fetal pulmonary physiology cannot be ruled out as a cause of PH.

The second category, *PH with left heart disease*, is the most common condition leading to PH in veterinary patients (Johnson, Boon, and Orton, 1999). Left-sided valvular or myocardial diseases, resulting in high left atrial and pulmonary venous pressures, dictate that PH be addressed via unloading agents (i.e., systemic arterial vasodilators) or agents that improve myocardial performance. Blood must be able to leave the left side of the heart to reduce “back pressure” (high pulmonary venous and arterial pressures) caused by poor left-sided cardiac output or impaired ventricular filling. Once optimal arterial dilation and cardiac performance have been achieved, pulmonary arterial dilators may result in additional benefit to the patient.

The third category of PH results from *disorders of the lungs or hypoxemia*. Inadequate oxygenation of systemic arterial blood caused by intrinsic lung disease, impaired control of breathing, or residence at high altitude causes PH. Inspired oxygen results in a subsequent decrease in PA pressures. Veterinary patients in this category of PH include those with interstitial lung disease, chronic obstructive pulmonary disease, disorders leading to alveolar hypoventilation, chronic exposure to high altitude, or neonatal lung disease. In humans survival depends on the severity of the pulmonary disease rather than on pulmonary hemodynamics; and long-term oxygen therapy or relocation from high altitude may be needed in addition to treatment of the underlying lung disease (Simonneau et al., 2004).

The fourth clinical category of PH results from *thrombotic or embolic diseases* and includes heartworm disease in veterinary patients. Embolization of the pulmonary arteries may also occur as a result of thrombi, neoplasia,

other parasites, or foreign material. In contrast to the previous categories, in which the pulmonary microcirculation is predominantly affected, thromboembolic disease usually involves the more proximal and larger segments of the pulmonary arterial tree. The therapeutic approach to thromboembolic PH is determined by the location of the emboli. Humans with large clots in major PAs require endarterectomy, a procedure not performed in veterinary patients. More peripheral emboli or thrombi can be treated with chronic pulmonary vasodilator therapy and lifelong anticoagulant therapy.

The fifth category is PH caused by *miscellaneous disorders*, which are rare in people and are of multiple etiologies, including sarcoidosis, histiocytosis X, lymph-angiomatosis, or compression of the pulmonary vessels. Conditions causing central pulmonary vein compression do occur in veterinary patients; they include neoplasia, lymphadenopathy, fibrosing mediastinitis, or granulomatous disease. Granulomas from blastomycosis have resulted in PH in dogs.

CLINICAL EVALUATION

Presentation

PH is reported more commonly in dogs than in cats. Studies in dogs have shown that males and females are affected equally, with an age range from 2 months to 17 years (Johnson, Boon, and Orton, 1999; Pyle, Abbott, and MacLean 2004). Breed distribution mirrors breeds prone to chronic valvular disease or airway disease. Historical problems are related to underlying lung or cardiac disease such as cough, dyspnea, tachypnea, wheezing, exercise intolerance, or exertional weakness or collapse. A surprisingly high number (23%) of dogs with PH presented with syncope in one study, yet 13% of 53 dogs were asymptomatic (Johnson et al., 1999).

Physical Examination Findings

Systolic murmurs over the mitral valve are present in the majority of dogs with PH, which is expected given the high prevalence of left-sided cardiac disease in affected patients. Murmurs of tricuspid regurgitation (TR) may also be detected; however, diastolic murmurs of pulmonic insufficiency are not usually audible. With severe PH the intensity of the tricuspid regurgitant murmur tends to increase, and often there is a palpable precordial thrill associated with the murmur. Auscultation of a tympanic or a split S_2 may result from delayed pulmonic valve (PV) closure relative to aortic valvular closure. Signs of pulmonary dysfunction, including cyanosis, tachypnea, orthopnea, or wheezing, may be present. Right-sided congestive heart failure (CHF), although less common than left-sided CHF in dogs with PH, may result in jugular venous distention, muffled heart and breath sounds ventrally caused by pleural effusion, and ascites.

Diagnosis

Thoracic Radiography

Radiographic abnormalities reflect the severity of disease and vary with the etiology of PH. Animals with primary

lung disease have parenchymal or bronchial abnormalities and secondary changes to the right heart. Right atrial (RA) and right ventricular (RV) enlargement, dilation of the PA segment, and pleural effusion may occur as PH worsens. Animals with valvular or myocardial disease of the left heart have radiographic changes typical of the underlying abnormality.

Electrocardiography

Electrocardiographic changes typical of right heart disease are not likely to occur until PH is moderate to severe. As the right ventricle becomes thicker than the left ventricle, a right axis deviation may develop in the frontal plane. P-pulmonale may occur with RA enlargement; and atrial arrhythmias, including atrial premature complexes or atrial fibrillation, may occur. Disease of the left heart, hypoxia, and ischemia may also contribute to a variety of other arrhythmias.

Doppler Echocardiography

Doppler echocardiography permits the estimation of right heart and PA pressures noninvasively, greatly lessening the need for cardiac catheterization. The ability to diagnose PH with Doppler echocardiography results from the tendency of the tricuspid and PVs to leak or become insufficient with high PA pressures. Since pressures across an open valve are equal if stenosis is not present, the RV systolic and PA systolic pressures are equal. If a RV-to-RA systolic regurgitant jet (i.e., TR) can be quantified, PA systolic pressure can be estimated (Fig. 156-1). Central venous pressure, usually unknown but estimated between 5 and 8 mm Hg in normal animals, may be added into the calculation; but this step is usually unnecessary in the determination of normal versus abnormal PA pressures.

A high-velocity TR jet is more likely to be present in PH than PV insufficiency (PI). However, in the absence of TR or if the regurgitant jet cannot be aligned with the Doppler cursor, a jet of PI may allow estimation of PA

Fig. 156-1 Continuous wave spectral tracing of a tricuspid regurgitant jet in a dog with pulmonary hypertension and chronic valvular disease obtained from the left apical view. The maximum right ventricular to right atrial velocity is 3.9 M/sec, and the pressure is 61 mm Hg. If RA pressure is estimated to be 5 mm Hg, then PA systolic pressure is 66 mm Hg.

diastolic pressure, except when the RV diastolic pressure is increased. A TR jet of 2.8 M/sec or greater corresponds to an RV-to-RA gradient of 31 mm Hg or greater (i.e., PA systolic hypertension) using the modified Bernoulli equation:

$$4 \times V^2 = \text{pressure (mm Hg)}$$

where V is the maximum velocity in meters/second. A PI jet of 2 M/sec or greater corresponds to a diastolic PA-to-RV pressure of 16 mm Hg or greater, reflecting PA diastolic hypertension.

The degree of PH can be categorized as mild, moderate, or severe based on the absolute PA systolic pressure. Pyle, Abbott, and MacLean (2004) defined mild PH as a systolic PA pressure between 30 and 55 mm Hg, moderate between 56 and 79 mm Hg, and severe 80 mm Hg or greater. Quantification of PA pressure may better define prognosis or the need for treatment, although Johnson, Boon, and Orton (1999) found that disease course was not related to the RV-to-RA pressure gradient.

Changes in RV function and structure associated with PH can be recognized with M-mode and two-dimensional echocardiography, including hypertrophy and dilation of the right ventricle, flattening of the septum as RV pressures exceed LV pressures, and a decrease in the diameter of the LV (Fig. 156-2, A and B). PH alters the timing of PV opening and closure, the pattern of PV motion, and the shape of the pulmonary flow velocity profile (Weyman, 1994; Schober and Baade, 2006). As PA pressure increases, the effect of atrial contraction on PV motion decreases, and the PV opens later than normal. PH causes a rapid valve opening and rapid increase in velocity, a more rapid acceleration with an earlier peak velocity relative to total ejection time, an earlier decrease in velocity, and less flow or even flow reversal in late systole (Fig. 156-3). Despite changes in the

pattern of flow, the peak outflow velocity usually does not differ from normal.

Other Diagnostic Tests

A stress or inflammatory leukogram may be present on a complete blood count, depending on the underlying etiology of the PH. Chronic hypoxemia may lead to an increased packed cell volume (PCV) and hemoglobin concentration, and nucleated red blood cells may be present. If right heart failure is present, alkaline phosphatase and increased alanine aminotransferase may occur secondary to passive congestion of the liver. If the etiology of PH is caused by chronic thromboembolic disease, D-dimer concentrations may support embolic disease if very high and rule out embolic disease if negative (Nelson, 2005).

THERAPEUTIC MANAGEMENT

The success of lowering PA pressure in veterinary patients depends on correctly identifying the underlying pathologic process and having medications that are orally effective. In humans the long list of drugs for PH has included nonselective vasodilators, inhaled oxygen, inhaled nitric oxide, diuretics, bronchodilators, prostacyclin analogs, endothelin receptor antagonists, and phosphodiesterase-5 (PDE5) inhibitors.

Vasodilators

The action of most vasodilators is not specific to the pulmonary circulation; therefore concomitant systemic vasodilation with hypotension has plagued this approach to PH treatment. In addition, systemic hypotension in the face of elevated RV chamber pressure may impair right

Figs. 156-2 A and B, Right parasternal short axis views of the LV at end-diastole before (2a) and after (2b) treatment with sildenafil for right-sided congestive heart failure caused by pulmonary hypertension and chronic valvular disease. There is flattening of the septum and a decrease in the size of the LV (**A**); PA systolic pressure was 72 mm Hg, and PA diastolic pressure was 55 mm Hg. Sildenafil treatment was added to enalapril and furosemide, and PA pressure decreased to 52/24 mm Hg within 12 hours. **B,** IVS flattening has disappeared, and the LV shape is normal. PA systolic pressure at this time was 40 mm Hg.

Fig. 156-3 Pulsed-wave pulmonary outflow velocity tracings in a normal dog (I), and dogs with PH (II and III). PH causes a rapid valve opening and rapid increase in velocity, an earlier peak velocity, an earlier decrease in velocity, and less flow or even flow reversal (III) in late systole. (Image courtesy Dr. Lynelle Johnson and Johnson L, Boon J, Orton EC: *J Vet Intern Med*, 1999.)

coronary artery perfusion and contribute to ischemic RV dysfunction (Mehta, 2003).

Prostanoids

Exogenous prostacyclin analogs (prostanoids) have been studied in humans with PAH. Prostacyclin is a potent vasodilator in both the pulmonary and systemic circulations and has antiplatelet activity. Chronic intravenous epoprostenol infusion, subcutaneous treprostinil infusion, inhaled iloprost, and oral beraprost all have been used with varying success in humans; but the method of delivery, short half-life, and expense make this drug class impractical for veterinary patients at this time.

Endothelin Receptor Antagonists

Bosentan (Tracleer, Actelion Inc.), a dual-receptor endothelin antagonist, is used singly or with other treatments in humans with PAH. Endothelin-1 is overexpressed in several forms of pulmonary vascular disease. Although endothelin mediates pulmonary vascular remodeling in a canine model of chronic embolic PH, bosentan is unlikely to be used in veterinary patients in the near future because of expense.

Phosphodiesterase-5 Inhibitors

The PDE5 inhibitor sildenafil (Viagra, Pfizer) has shown efficacy in reducing PA pressure. Phosphodiesterases are a superfamily of enzymes that inactivate cyclic adenosine monophosphate and cyclic guanosine monophosphate, the second messengers of prostacyclin and nitric oxide. The phosphodiesterases have different tissue distributions and substrate affinities, with abundant expression of PDE5 in lung tissues.

Currently there are three PDE5 inhibitors on the market for erectile dysfunction in men. In humans all three PDE5 inhibitors cause significant pulmonary vasorelaxation, with maximum effects being obtained after 40 to 45 minutes with vardenafil (Levitra, Bayer Pharmaceuticals), 60 min with sildenafil, and 75 to 90 min with tadalafil (Cialis, Lilly ICOS, LLC) (Ghofrani et al., 2004). Sildenafil and tadalafil, but not vardenafil, cause a significant reduction in the pulmonary-to-systemic vascular resistance ratio. Significant improvement in arterial oxygenation (equal to nitrous oxide inhalation) is only noted with sildenafil (Ghofrani et al., 2004). The effect of sildenafil on pulmonary vasculature is independent of the underlying cause of PH.

Sildenafil has been used successfully in dogs and cats with moderate-to-severe PH secondary to either left heart disease or primary lung disease. The currently recommended starting dosage is 1 mg/kg every 8 hours orally; dosages as high as 3 mg/kg orally every 8 hours have been tolerated but should be used only with careful monitoring of arterial blood pressure. Sildenafil is available in 25-, 50-, and 100-mg tablets, which are all approximately \$10 in the United States, regardless of tablet size. Veterinary pharmacies can reformulate the 100-mg tablets into appropriately sized capsules. Information regarding adverse effects in dogs and cats, as well as dosage adjustment, is not currently available. Response to PDE5 inhibitors results in a decrease in measured TR or PI velocity, improvement in two-dimensional echocardiography abnormalities, increase in exercise tolerance, reduction in collapsing or syncopal episodes, and improved respiratory effort.

Treatment Recommendations Based on the Clinical Category of PH

Optimal treatment of PH depends on the underlying disease or condition. A major reason for the development of the clinical classification scheme was to tailor the approach to treatment based on the underlying disease process.

Pulmonary Arterial Hypertension

Pulmonary arterial vasodilators such as the PDE5 inhibitors are the treatment of choice for diseases characterized by lesions confined to the small arteries and arterioles. If left-to-right shunting lesions are present, correction should be performed if possible. If polycythemia is present because of right-to-left shunting disease, treatment with hydroxyurea in addition to PDE5 inhibitors is recommended to maintain PCV between 62% and 66%.

Heartworm disease and concomitant endarteritis should be treated with melarsamine HCl and low-dose aspirin, with care taken to protect the gastrointestinal track from aspirin-induced hemorrhage. In addition, the

PDE5 inhibitors provide a new therapeutic option in dogs with clinical signs caused by heartworm disease and PH.

Pulmonary Hypertension With Left Heart Disease

Diseases of the left heart, either valvular or myocardial, should be treated with cardiovascular drugs that reduce afterload, increase contractility, or both. Systemic arterial blood pressure measurements should be performed serially to produce optimal systemic vasodilation without signs of hypotension. Arterial vasodilators such as nitroprusside, angiotensin-converting enzyme inhibitors, and hydralazine can be used in combination to lower arterial blood pressure. Pimobendan, which is an "inodilator" with both systemic arterial and venous vasodilating and positive inotropic effects, also causes pulmonary arterial dilation. Once myocardial performance and arterial vasodilation are optimal, the addition of sildenafil or another PDE5 inhibitor may increase exercise tolerance and lessen syncope or other clinical signs in dogs with PH caused by left heart disease.

Pulmonary Hypertension Associated With Lung Diseases and/or Hypoxemia

Treatment of PH associated with lung disease or hypoxemia in humans is focused on the pulmonary problem rather than the vascular derangement and usually includes ambulatory oxygen administration. Dogs with chronic bronchitis should be managed with antimicrobials or antiinflammatory doses of prednisone, as dictated by cytology and culture of the airways. Administration of bronchodilators may lessen respiratory muscle fatigue and clinical signs. Pulmonary fibrosis or other interstitial lung disease, which is more likely to result in severe PH, should be treated aggressively with immunosuppressive, immunomodulatory, or antifibrotic treatment based on lung biopsy, culture, and histology. Ambulatory oxygen therapy is not a practical option in veterinary patients with lung disease and PH; therefore treatment of the underlying disease remains the cornerstone of treatment. Phosphodiesterase inhibitors should be considered in patients with PH and clinical signs refractory to specific pulmonary therapy.

Pulmonary Hypertension Caused by Chronic Thrombotic or Embolic Disease

The treatment approach to PH caused by thromboembolic disease varies with the location of the emboli and the underlying cause. Diseases (e.g., hyperadrenocorticism, heartworm disease) predisposing to pulmonary thromboembolism should be treated if possible. If the underlying disease process cannot be corrected, lifetime anticoagulant therapy should be administered (see Chapter 155) in addition to pulmonary arterial vasodilators (e.g., PDE5 inhibitors) for emboli in distal pulmonary arteries. Emboli in proximal pulmonary arteries are usually peracute and fatal in veterinary patients.

Miscellaneous Causes of Pulmonary Hypertension

PH caused by compression of the pulmonary vessels may occur in veterinary patients as a result of neoplasia,

granulomatous disease, or lymphadenopathy. The etiology of the compressive lesion (e.g., blastomycosis, lymphosarcoma) must be identified to treat appropriately and cause regression of the mass; only then can PH be managed. Since the disorder is outside of the vessel, the use of antithrombotic drugs or PDE5 inhibitors would not be of benefit.

PROGNOSIS

The prognosis of animals with PH is variable and depends on the ability to treat or manage the underlying disease or condition. Animals with PH and CHF caused by left-sided valvular disease have a favorable prognosis and may live for over a year with careful attention to congestive signs, heart rate and rhythm, arterial blood pressure, serum electrolytes, and renal function. Dogs with right-to-left shunting congenital heart defects may live 4 to 5 years with management of polycythemia and PH. Animals with or severe lung disease or thromboembolic disease often have a poor prognosis because of disease progression. Finally, dogs with PH resulting from compressive lesions have a favorable prognosis if blastomycosis is the cause of the granuloma, whereas those with neoplastic compression of the pulmonary vessels have a guarded prognosis.

Nutritional Management of Heart Disease

LISA M. FREEMAN, *North Grafton, Massachusetts*

GENERAL NUTRITIONAL ISSUES FOR ANIMALS WITH HEART DISEASE

For many years the role of nutrition in the management of heart disease consisted primarily of feeding a low-sodium diet. We now know that severe sodium restriction is not necessary in all animals with heart disease. It is also becoming apparent that supplementation of certain nutrients, either to correct a deficiency or to provide pharmacologic effects, may have profound benefits in animals with heart disease. Research is now beginning to show that nutrition can modulate heart disease by slowing the progression, minimizing the number of medications required, improving quality of life, or in rare cases actually curing the disease. Therefore attention to diet at all stages of heart disease is critical for optimal care of the cardiac patient.

A single diet does not work for all animals with heart disease, and dietary modifications need to be individualized. Patients with heart disease vary in their clinical signs, laboratory parameters, and food preferences, which all affect diet selection. For example, more severe sodium restriction would be required for a cat with congestive heart failure (CHF) than for a cat with asymptomatic heart disease. Animals with heart disease may be hyperkalemic, hypokalemic, or normokalemic, which influences the choice of diet. Concurrent diseases also alter diet choice and are present in many animals with heart disease (61% of dogs in one study; Freeman et al., 2003).

Based on these patient parameters, one or more diets can be selected for the individual patient. Currently a number of commercial veterinary cardiac diets are available, the specific characteristics of which vary, but they are all moderately to severely sodium restricted. Some cardiac diets also may include supplemental taurine, carnitine, arginine, antioxidants, or n-3 fatty acids. In some cases a veterinary diet designed for another disease or an over-the-counter diet may have the properties desired for an individual patient. I generally try to recommend multiple diets so the owner can determine which is most palatable to the pet. Having a number of choices is particularly beneficial for animals with severe CHF, a condition in which loss of appetite is common.

In addition to the pet food(s) selected, the owner must also receive careful instructions on treats and table food. In some cases animals may be eating an ideal pet food but are getting large amounts of sodium from treats. In one study over 90% of dogs with heart disease received treats, and these dogs were receiving up to 100% of

their dietary sodium from them (Freeman et al., 2003). Examples of appropriate treats are shown in Table 157-1.

Therefore a diet must be selected that has the desired nutritional properties and palatability, but it also is important to devise an overall dietary plan that includes a satisfactory method for administering medications. Most people use food for this purpose, and the most commonly used foods are high in sodium (e.g., cheese, hot dogs, lunch meats). Therefore examples of appropriate methods of administering medications should be provided to the owner (Box 157-1). Including all sources of dietary sodium intake in the overall diet plan is important to achieve success with nutritional modifications.

All dietary changes should be made gradually over a period of 3 to 5 days. It may be difficult to make major dietary changes while the patient is sick or hospitalized. Often it is better to wait several days until the patient's condition has improved and then initiate the change. Food aversions develop in ill humans, and such aversions may prevent adequate intake of the food over the long term. It also is important to instruct the owner to notify the veterinarian if the patient does not eat adequate amounts of the new food so that other options can be devised.

NUTRITIONAL MODIFICATIONS BASED ON SEVERITY OF DISEASE

Asymptomatic Heart Disease

Nutritional therapy for dogs and cats with asymptomatic heart disease has been like a pendulum over the years. Initially very low-sodium diets were recommended to be fed when a heart murmur was first detected. Veterinarians then moved toward the approach that severe sodium restriction may not be ideal at this stage because of early activation of the renin-angiotensin-aldosterone (RAA) system, and this led to the idea that no nutritional modifications can or should be made for animals with asymptomatic heart disease. Veterinarians are now swinging back toward the middle because new research is supporting the idea that dietary modification in early heart disease might be beneficial and the nutritional management of animals with asymptomatic heart disease should not be ignored.

One of the earliest and major compensatory responses in heart disease is activation of the RAA system; and sodium restriction can further elevate renin, angiotensin, and aldosterone. Thus severe sodium restriction in animals with early heart disease theoretically could be

Table 157-1

Examples of Low-Sodium Treats

Treat	Kilocalories per treat	Sodium (mg/treat)
Dogs		
Science Diet Adult Treats (medium)	20	13
Iams Original Formula Biscuits (small)	22	10
Hill's Prescription Diet Canine Treats	13	5
Stewart Fiber Formula Dog Biscuits (medium)	25	5
Baby carrots	4	4
Alpo Healthy Snacks Variety Snaps With Real Meat	13	1
Apple (raw, 1 slice) or orange (1 section)	10	0
Cats		
Purina Whisker Lickin's Brand Crunchy Cat Treats Tartar Control (all flavors)	3	3
Stewart Fiber Formula Cat Treats	1	1

detrimental by triggering early and excessive activation of the RAA system. I recommend only mild sodium restriction in asymptomatic heart disease (<100 mg/100 kcal for animals in International Small Animal Cardiac Health Council (ISACHC) Stage 1a and less than 80 mg/100 kcal for animals in ISACHC Stage 1b; see Chapter 171). However, this is an opportune time to begin talking to the owner about the animal's overall dietary patterns (i.e., the pet food, treats, table food, and how medications are administered) since it is generally much easier to institute dietary modifications when the animal is asymptomatic.

In addition to mild sodium restriction, the other main goal is to achieve or maintain optimal body condition. An estimated 25% to 40% of dogs and cats in the United States are overweight or obese. Therefore some animals with heart disease, particularly those in the asymptomatic stages,

will be obese. Obesity can exacerbate heart disease, and weight loss in severely obese animals with heart disease usually results in a less dyspneic and a more active pet. Weight reduction programs can be challenging and run a high risk of failure without careful planning of a comprehensive program and regular monitoring and adjustment.

Finally, there is potential for benefit with nutritional modification in the asymptomatic animal. One recent study compared a moderately reduced sodium cardiac diet that was enriched with n-3 fatty acids, antioxidants, arginine, taurine, and carnitine to a placebo diet in dogs with asymptomatic chronic valvular disease (CVD) (Freeman et al., 2006). The cardiac diet increased circulating levels of key nutrients (e.g., antioxidants, n-3 fatty acids) and also moderately reduced cardiac size. This reduction in cardiac size did not appear to be an effect of sodium restriction. Future studies will help to build understanding of the role of nutritional modification in this early stage of disease.

Mild-to-Moderate Congestive Heart Failure

When CHF develops, additional nutritional concerns arise for the dog or cat with heart disease. Maintaining optimal body condition is of primary importance in the animal with CHF. Although obesity still can be present at this stage, animals with CHF more commonly begin to demonstrate weight loss. This weight loss, or cardiac cachexia, is unlike that seen in a healthy animal, which loses primarily fat. In an animal with CHF the primary tissue lost is lean body mass. The term *cachexia* does not necessarily equate with an emaciated, end-stage patient; and there is a spectrum of severity with cachexia. In the early stages it can be very subtle and may even occur in obese animals (i.e., an animal may have excess fat stores but still lose lean body mass). Loss of lean body mass usually is first noted in the epaxial, gluteal, scapular, or temporal muscles. Cardiac cachexia typically does not occur until CHF has developed but can occur with any underlying cause of CHF (e.g., dilated cardiomyopathy [DCM], CVD, congenital heart diseases). Cardiac cachexia is a common finding in animals with CHF and has deleterious effects on strength, immune function, and survival; thus it is important to recognize cachexia at an early stage for better opportunities to manage it effectively.

The loss of lean body mass in cardiac cachexia is a multifactorial process caused by anorexia, increased energy requirements, and an increased production of inflammatory cytokines such as tumor necrosis factor (TNF) and interleukin-1 (IL-1). These cytokines cause anorexia, increase energy requirements, and increase the catabolism of lean body mass. In addition, TNF and IL-1 also cause cardiac myocyte hypertrophy and fibrosis and have negative inotropic effects.

The nutritional management of animals with cardiac cachexia consists primarily of providing adequate calories and protein and modulating cytokine production. One of the most important issues for managing anorexia (which is defined here to include both a complete and partial loss of appetite) is to optimize medical therapy. An early sign of worsening CHF or the need for medication adjustment is a reduction in food intake in an animal that has previously been eating well. Medication side

Box 157-1**Recommended Methods for Medication Administration**

- Teach the owner to pill the animal without using foods.
- Use a Pet Piller or Pet Pill Gun (Jorgensen Laboratories).
- Switch from pills to a compounded, flavored liquid medication (NOTE: the pharmacokinetics may be altered).
- Use low-sodium foods to insert the pills before administration.
- Add to meat, home-cooked, without salt (not lunch meats).
- Fresh fruit (e.g., banana, orange, melon, berries).
- Add to low-sodium canned pet food.
- Add to peanut butter (labeled as "no salt added").

effects such as digoxin toxicity or azotemia secondary to angiotensin-converting enzyme (ACE) inhibitors or overzealous diuretic use also can cause anorexia. Providing a more palatable diet can help to improve appetite (e.g., switching from a dry food to a canned food, changing to a different brand, having a balanced cooked homemade diet formulated by a veterinary nutritionist). It also may be useful to use flavor enhancers to increase food intake (e.g., yogurt, maple syrup, or applesauce in dogs; home-cooked meats or fish in cats). Modulation of cytokine production also can be beneficial for managing cardiac cachexia. Supplementation of fish oil, which is high in n-3 fatty acids, can decrease inflammatory cytokine production and improve cachexia (see following paragraphs).

Protein

As early as the 1960s protein restriction was recommended for animals with CHF to reduce the “metabolic load” on the kidneys and liver. Restricting protein is actually detrimental to the animal with CHF because it can contribute to lean body mass loss and malnutrition. Animals with CHF should not be protein restricted unless they have concurrent advanced renal disease. Some of the diets designed for dogs with cardiac disease are very low in protein (this is not a problem with feline cardiac diets). Similarly, protein-restricted renal diets are sometimes recommended for animals with heart disease because these diets often (but not always) are moderately sodium restricted. Unless concurrent disease dictates otherwise, high-quality protein should be fed to meet canine (5.1 g/100 kcal) or feline (6.5 g/100 kcal) minimums. This should be a primary goal in animals with heart disease, particularly as CHF becomes more severe.

Another important issue with regard to protein is the still widespread misconception that dietary protein should be restricted in early renal disease. Some dogs receiving ACE inhibitors develop azotemia, although this is relatively uncommon. Azotemia occurs more frequently when ACE inhibitors are used in conjunction with diuretics, but in a small number of dogs azotemia can develop from ACE inhibitors alone. When concurrent ACE inhibitor and diuretic use causes azotemia, reduction of the diuretic dose is indicated. A protein-restricted diet is not recommended in this situation unless medication changes do not correct the problem and renal disease progresses.

Fat

In addition to being a source of calories and essential fatty acids, fat also can have significant effects on immune function, inflammatory mediator production, and hemodynamics. Most canine and feline diets contain primarily n-6 fatty acids (e.g., linoleic acid, arachidonic acids). The n-3 fatty acids eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) normally are found in very low concentrations in the cell membrane compared to the n-6 fatty acids, but they can be increased by a food or supplement enriched in n-3 fatty acids. The benefit of having a higher concentration of n-3 fatty acids in the membranes is that breakdown products of the n-3 fatty acids (eicosanoids) are less potent inflammatory mediators than eicosanoids derived from n-6 fatty acids. This decreases the production of cytokines and other inflammatory mediators. Fish oil reduces the production of TNF and IL-1 and improves muscle mass. In some animals

fish oil supplementation also improves appetite. Another potential benefit is that n-3 fatty acids have antiarrhythmic effects.

Although an optimal dose of n-3 fatty acids has not been determined, I currently recommend a daily dosage of 40 mg/kg of EPA and 25 mg/kg of DHA for animals with anorexia or cachexia. Unless the diet is one of a few specially designed therapeutic diets, supplementation is necessary to achieve this n-3 fatty acid dose. When recommending a fish oil supplement, it is important to know the exact amount of EPA and DHA in a specific fish oil brand since supplements vary widely. However, the most common formulation of fish oil is 1-g capsules that contain approximately 180 mg of EPA and 120 mg of DHA. At this concentration fish oil can be administered at a dose of 1 capsule per 10 pounds of body weight to achieve my recommended EPA and DHA dosage. Fish oil supplements should always contain vitamin E as an antioxidant, but other nutrients should not be included to avoid toxicities. Cod liver oil and flaxseed oil should not be used to provide n-3 fatty acids to dogs and cats.

Sodium

Sodium restriction is one method, along with the use of diuretics and venous vasodilators, to treat excessive increases in preload in patients with CHF. In the 1960s, when few medications were available for treating animals with CHF, dietary sodium restriction was one of the few methods of reducing fluid accumulation. In this situation severe sodium restriction clearly was beneficial in reducing signs of congestion. However, with the current availability of newer and more effective medications, the role of severe sodium restriction in early CHF (ISACHC stage 1 or 2) is no longer clear. I currently recommend moderate sodium restriction (i.e., 50 to 80 mg/100 kcal) for animals with ISACHC stage 2 heart disease.

Most owners are unaware of the sodium content of pet and human foods and need very specific instructions regarding appropriate pet foods, acceptable low-salt treats, and methods for administering medications. Owners also should be counseled on specific foods to avoid such as baby food; bread; canned vegetables (unless “no salt added”); cheeses, including “squirtable” cheeses (unless specifically labeled “low sodium”); condiments (e.g., ketchup, soy sauce); lunch meats and cold cuts (e.g., ham, corned beef, salami, sausages, bacon, hot dogs); most pet foods and treats; pickled foods; pizza; processed foods (e.g., potato mixes, rice mixes, macaroni and cheese); snack foods (e.g., potato chips, packaged popcorn, crackers); and soups (unless homemade without salt). Mildly to moderately reduced dietary sodium can be achieved with a veterinary diet designed for animals with early cardiac disease or with certain diets designed for use in senior pets. If using a diet designed for senior pets, it is important to look at the characteristics of the individual product. There is no legal definition for a senior diet; thus the levels of calories, protein, sodium, and other nutrients can vary dramatically between different companies’ products.

Potassium and Magnesium

Potassium and magnesium are nutrients of concern in cardiac patients because depletions of these electrolytes can cause cardiac arrhythmias, decreased myocardial

contractility, and muscle weakness and can potentiate the adverse effects of cardiac medications. Many of the medications used in animals with CHF such as loop diuretics (e.g., furosemide) and thiazide diuretics (e.g., hydrochlorothiazide) can predispose a patient to hypokalemia. Inadequate dietary intake of potassium, which occurred in nearly half of dogs with heart disease in one study, also can predispose an animal to hypokalemia (Freeman et al., 2003). However, it is also important to note that the increased use of ACE inhibitors, which results in renal potassium sparing, has made hyperkalemia just as likely as hypokalemia in animals with CHF. In addition, spironolactone, an aldosterone antagonist and potassium-sparing diuretic, is being used with greater frequency in dogs with heart disease and can cause hyperkalemia. Finally, some commercial cardiac diets are high in potassium, which can exacerbate hyperkalemia.

Magnesium plays a critical role in normal cardiovascular function; and many of the medications used to treat cardiac conditions, including digoxin and loop diuretics, are associated with magnesium depletion in people. Therefore animals with CHF have the potential to develop hypomagnesemia. Studies have reported variable prevalence rates of hypomagnesemia (from 2% to over 50%) in dogs with heart disease.

Serum potassium should be monitored routinely in CHF patients, particularly those receiving an ACE inhibitor or large doses of diuretics. Serum magnesium concentrations also should be measured, but clinicians should be aware that serum magnesium concentrations are a poor indicator of total body stores. Nonetheless, serial evaluations in an individual patient may be useful, especially in patients with arrhythmias or in those taking high doses of diuretics. Diets range greatly in their potassium content; thus if hypokalemia or hyperkalemia is present, a diet with a higher or lower potassium content, respectively, should be selected. Similarly, diets high in magnesium may be beneficial in a hypomagnesemic animal.

Severe or Refractory Congestive Heart Failure

In severe CHF greater restriction of dietary sodium (<50 mg/100 kcal) may allow lower dosages of diuretics to be used to control clinical signs. To achieve this level of sodium restriction it may be necessary to feed a commercial cardiac diet. Typically these diets are severely restricted in both sodium and chloride; levels of other nutrients vary with the individual product. There also is a higher risk for potassium and magnesium abnormalities in severe CHF; thus monitoring of electrolytes is important.

At this stage of disease cardiac cachexia becomes more common; thus it is critical to maintain adequate calorie and protein intake. This can be a challenge since appetite in severe CHF is often cyclical and owners should be warned that appetite can be highly variable. Another issue to consider is that anorexia in an animal that has been eating can be an early sign of worsening disease or the need for medication adjustment and should trigger a reevaluation. In addition to optimization of medical therapy, offering multiple choices of appropriate pet foods, a homemade diet, or even single food items that can increase calorie intake without exacerbating the underlying disease (e.g., home-cooked meat, low-sodium breakfast cereal, or Clif

Bars) can be very useful. Palatability enhancers also can be very helpful for pets with severe CHF (e.g., cooked fish, low-sodium tuna, or cooked meat for cats; cooked meat, yogurt, applesauce, or maple syrup for dogs). Encouraging the owner to try offering foods at different temperatures may increase food intake in some animals (e.g., warmed versus room temperature versus cold). n-3 fatty acid supplementation also can be beneficial in some animals in which appetite is poor. Other tips that may increase food intake include providing smaller, more frequent meals; feeding the recommended diet(s) from the owner's plate; or putting the recommended diet(s) into a treat jar.

SPECIAL SITUATIONS

Feline Dilated Cardiomyopathy

The role of taurine deficiency in feline DCM has been well described, and there has been a dramatic decline in the incidence of the disease since the late 1980s. Most current cases of feline DCM appear to be independent of taurine status. Still taurine deficiency should be suspected whenever the diagnosis of feline DCM is made. A complete diet history should be obtained because cats that are eating a vegetarian diet or other unconventional diet are at higher risk for taurine deficiency. Even commercial vegetarian diets, the ingredient lists of which include taurine, can be severely taurine deficient. Plasma and whole blood taurine should be analyzed, and treatment with taurine (125 to 250 mg orally [PO] q12h) should begin concurrent with medical therapy. If the cat is eating an unconventional diet, the owner also should be counseled to switch to a nutritionally balanced meat-based commercial cat food.

Canine Dilated Cardiomyopathy

Supplementation of certain nutrients, either in the diet or in the form of dietary supplements, is most often proposed for dogs with DCM. Although some studies have been conducted in these areas, making recommendations can be difficult because there are many unsubstantiated claims for dietary supplements that owners find when researching DCM. A discussion of the role for some of these nutrients in canine DCM follows:

Taurine

Unlike cats, dogs are thought to be able to synthesize adequate amounts of taurine endogenously, and taurine is not considered a requirement in canine diets. Although typical breeds with DCM (e.g., Doberman pinscher, boxer) do not appear to have reduced taurine concentrations, taurine deficiency has been documented in some dogs of certain breeds with DCM, such as the American cocker spaniel, Newfoundland, and golden retriever. Taurine deficiency may occur more commonly in certain breeds because of higher requirements or breed-specific metabolic abnormalities, but diet also may play a role. Lamb meal and rice and high-fiber or very low-protein/low-taurine diets have been associated with taurine deficiency, although the exact role of diet is not yet known.

The benefits of taurine supplementation are not as clear in canine DCM as in feline DCM. Although several

small studies have shown some improvements in clinical or echocardiographic parameters in taurine-deficient dogs supplemented with taurine, the response is generally not as dramatic as is seen in cats with taurine deficiency-induced DCM (Kittleson et al., 1997). Although ongoing research in this area will help to better understand this disease and make better recommendations in the future, I currently recommend measuring plasma and whole blood taurine concentrations in dogs with DCM that are of high risk (e.g., cocker spaniel, Newfoundland, golden retriever) or atypical (e.g., corgi, basset hound) breeds. In addition, taurine concentrations should be measured in dogs with DCM that are eating lamb meal and rice-based diets, high-fiber diets, or diets that are highly protein restricted. Although the extent of benefits of supplementation is not yet clear, I recommend taurine supplementation until plasma and whole blood taurine concentrations on the patient are available. The optimal dose of taurine for correcting a deficiency has not been determined, but the dosage currently recommended is 500 to 1000 mg every 8 to 12 hours.

L-Carnitine

L-Carnitine plays an important role in long-chain fatty acid metabolism and energy production. Carnitine is in high concentrations in the myocardium, and carnitine deficiency syndromes can be associated with primary myocardial disease in humans. Carnitine deficiency was reported in a family of boxers in 1991. Since that time L-carnitine has been supplemented in some dogs with DCM, but no blinded prospective studies have been done. However, one randomized, double-blind, placebo-controlled study in humans with DCM showed improved 3-year survival in patients receiving L-carnitine supplementation. One of the limitations on progress in the study of carnitine deficiency is that myocardial concentrations must be measured to document a deficiency since plasma concentrations are often normal even in the face of myocardial deficiency.

L-carnitine supplementation has few side effects, but it is an expensive supplement, and this may be a significant deterrent for some owners. I offer the option of L-carnitine supplementation to owners of dogs with DCM, especially boxers but do not consider it essential. The minimum or optimal dose of L-carnitine necessary to replete a dog with low myocardial carnitine concentrations is not known, but the dosage that has been recommended is 50 to 100 mg/kg orally every 8 hours.

Antioxidants

Although antioxidants have received a great deal of attention in the popular press in terms of preventing and treating cardiovascular diseases, most of the research in human cardiology has been on coronary artery disease. Antioxidants are produced endogenously but also can be supplied exogenously if there is an imbalance between the levels of oxidants produced and the antioxidant protection available. The major antioxidants include enzymatic antioxidants (e.g., superoxide dismutase, catalase, glutathione peroxidase) and oxidant quenchers (e.g., vitamin C, vitamin E, and β -carotene). Recent studies have shown that, in dogs with CHF from either DCM or CVD, there is an imbalance between oxidant production and antioxidant protection. Supplemental antioxidants are now included in many commercial veterinary diets, including at least one cardiac

diet. The effect of antioxidant supplementation in dogs and cats with CHF is not yet known; however, this may hold promise for the future.

Coenzyme Q10

The roles of coenzyme Q10 in energy production and as an antioxidant have prompted some investigators to propose coenzyme Q10 deficiency as a possible cause for DCM. Coenzyme Q10 supplementation has anecdotally been reported to be beneficial; but most of the human studies of coenzyme Q10 supplementation have not been well controlled, and results are conflicting. The current recommended (but empiric) dosage in dogs is 30 mg orally BID, although up to 90 mg orally BID has been recommended for large dogs. The purported benefits of supplementation include correction of a deficiency, improved myocardial metabolic efficiency, and increased antioxidant protection. Controlled prospective studies are necessary to accurately judge the efficacy of this often expensive supplement.

Dietary Supplements: General Issues

In many cases the desired nutrient modifications can be achieved through diet alone. However, supplementation of certain nutrients may be desirable if they are not in a particular diet or not at high enough levels in the diet to achieve the desired effect. It is important to be aware that dietary supplements do not require proof of safety, efficacy, or quality control to be marketed. Therefore careful selection of type, dose, and brand is important to avoid toxicities or complete lack of efficacy. Much additional information is needed to define the role of dietary supplements in heart disease, when they should be used, when they should not be used, and optimal dosages.

Another important issue with the administration of dietary supplements is that they should not take the place of standard cardiac medications. Animals with severe CHF may already be receiving many pills each day, and it may not be clear to owners that it is more important to give the cardiac medications than the dietary supplements. In situations in which pill administration is becoming overwhelming for an owner, the veterinarian can assist the owner in determining which dietary supplements have the least potential benefits and can be discontinued.

Syncope

MARC S. KRAUS, *Ithaca, New York*
CLAY A. CALVERT, *Athens, Georgia*

The evaluation of syncope in animals is often challenging. Difficulties arise from the very nature of syncope because these events are often unpredictably sporadic, infrequent, and characterized by intersyncopal periods that are often unremarkable. Syncope is defined as a sudden loss of consciousness associated with loss of postural tone from which recovery is spontaneous. Allowing for the occasional exception such as hypoglycemia, the common denominator leading to all forms of syncope is a decrease or brief cessation of cerebral blood flow. *Presyncope* is a term used to describe episodic reallimb or generalized weakness, ataxia, or an altered level of consciousness. Presyncope is associated with a less severe or more transient cerebral insult. Severe heart rhythm disturbances are probably the most common causes of syncope in dogs and cats.

IS IT SYNCOPES?

Distinguishing syncope from seizure can be difficult. Situational triggers, prodromal symptoms, signs that occur during the episode, and the events that follow provide clues for differential diagnosis. Collapse episodes that are precipitated by exercise, stress, startle, cough, gag, deglutition, emesis, micturition, defecation, and pain are most likely syncope rather than seizure. Disorientation after the event with slow recovery of normal consciousness is more common with seizures. However, protracted cerebral hypoxia resulting from cardiac arrhythmia may also be followed by slow recovery. Differentiating seizure from syncope can be confounded by the possibility of "hypoxic convulsive syncope" caused by profound cardiac arrhythmia. Cats may demonstrate focal facial twitches that appear very much like a focal seizure. Syncope or presyncope without prodrome or violent tonic-clonic activity and with quick recovery suggests a heart rhythm disturbance. Although often associated with flaccid collapse, syncope caused by arrhythmia can be associated with extensor rigidity, opisthotonus, and spontaneous urination or defecation. Hypersalivation is rarely associated with syncope caused by heart rhythm disturbances.

NEUROCARDIOGENIC (VASODEPRESSOR) SYNCOPES

Neurocardiogenic syncope (also called the reflex-mediated syncope) is the result of an incompletely understood adrenergic-stimulated baroreceptor reflex mechanism. Sympathetic stimulation normally leads to vasoconstriction, increased heart rate, and increased cardiac contractility. However, in

humans in the presence of dehydration, volume underloading of the left ventricle, and orthostasis, increased ventricular contractility (empty ventricle syndrome) stimulates afferent vagal traffic to the brainstem from ventricular mechanoreceptors. The next step in the reflex is sympathetic withdrawal, which results in vasodilation (vasodepressor syncope) along with increased vagal efferent traffic that results in bradycardia. This can be considered an abnormal and inappropriate activation of the baroreceptor reflex.

In dogs neurocardiogenic bradycardia and syncope are usually precipitated by fight, flight, fright, or startle situations. Furthermore, it is not evident that dehydration is a predisposing factor. In fact, in the most common scenario (i.e., the elderly small dog with advanced mitral valve disease), the patient is volume expanded and is often not being administered drugs. Nonetheless the hyperdynamic left ventricle of the patient with advanced mitral valve regurgitation may, under the influence of sympathetic surge, simulate the empty ventricle syndrome because of further increase in contractility and massive regurgitation. When vagal afferent receptors at the left atrium-pulmonary venous junctions are suddenly stretched by increased right ventricular output, they may also trigger the reflex. Reflex-mediated syncope also may develop in cases of ventricular outflow obstruction.

The common denominator of all neurally mediated syncopes is vagal input to the cardiovascular center of the brainstem with subsequent sympathetic withdrawal, usually accompanied by vagal outflow. In the clinical setting in dogs, the hallmark sign is bradycardia, including sinus bradycardia, sinus arrest, or transient atrioventricular (AV) block. Documentation of vasodilation caused by sympathetic withdrawal is problematic. For this reason the common assumption is that these syndromes are caused mainly by bradycardia. However, we have observed "apparent" neurocardiogenic syncope in the absence of bradycardia. Furthermore, weakness, pallor, and lethargy persist in some patients after bradycardia has resolved; these patients may well be hypotensive from protracted vasodilation, as is often observed in humans.

The "broad" diagnosis of neurally mediated syncope is usually presumptive and based on the triggering situation and underlying disorders such as bronchial lung disease, advanced mitral valve disease, dilated cardiomyopathy, or breed predilection. Cough, emesis, micturition, defecation, and exertional situations are common triggers to the "situational syncopes." Electrocardiogram (ECG) or auscultation is required for documentation of bradycardia; and an indwelling arterial catheter or reliable, noninvasive blood pressure device is required to document hypotension

(of course this is rarely possible). The 24- to 48-hour ambulatory ECG and even a 5- to 7-day ECG event recording are somewhat insensitive tests since most episodes are infrequent. Usually the precipitating exertional situations are exertion with excitement, inactivity to sudden “normal” activity, startle, climbing stairs, physical restraint, bathing or grooming, or barking-jumping with excitement. In young adult golden retrievers most episodes occur during walking with the owner and are precipitated by an excitement event (e.g., seeing another animal or straining at the leash).

ETIOLOGY OF SYNCOPE

Many disorders can result in syncope (Box 158-1); they can be categorized into cardiac and noncardiac causes. Hypoglycemia, hypoxia, and anemia are the most common metabolic causes of syncope. Addison’s disease rarely causes episodic signs but rather causes progressive and protracted signs.

By far the most common recognized cause of syncope is disturbance of the heart rhythm. Advanced heart block is the most common cause of syncope across all breeds and ages. On the other hand, sick sinus syndrome is the most common cause of bradycardia and syncope in middle-aged and older American cocker spaniels, West Highland white terriers, and miniature schnauzers. Situational bradycardia and syncope are common in small dogs of all ages but most common in older patients. With advanced mitral regurgitation and high preload, it is precipitated by a surge of adrenalin caused by fight, flight, and fright situations. Respiratory arrest, white mucous membranes, and cyanosis occur during severe and protracted bradycardia (and presumably vasodilation). Frequently the owner believes that death has occurred. Most episodes last for only seconds to

minutes. However, when pulmonary edema is beginning, bradycardia can persist for as long as 30 minutes. As with most situational syncopes in elderly small dogs, neurocardiogenic bradycardia is seldom lethal. It is a warning of high preload, impending pulmonary edema, and a need to aggressively unload the heart. It can be lethal when precipitated in the hospital setting by physical restraint.

Neurocardiogenic bradycardia (syncope) can also occur in “normal” dogs, particularly in golden retrievers, boxers, and dogs undergoing attack training. In boxers it seems to have a bimodal age of first occurrence: 6 to 24 months of age and 7 to 10 years of age. It is usually triggered by exertion coupled either with excitement or startle and can occur without evidence of cardiomyopathy (based on the absence of ventricular arrhythmias, cardiac enlargement, and decreased contractility). However, since both syndromes are common, each can occur in the same dog. In such patients the differential diagnosis is confounding and requires Holter recording or event monitor recording. In our experience Holter recordings in boxers and Doberman pinschers performed within 48 hours following syncope caused by ventricular tachycardia usually contain thousands of ventricular premature contractions (PVCs) with couplets, triplets, and nonsustained ventricular tachycardia.

Neurocardiogenic bradycardia and syncope also occur in Doberman pinschers wherein it is a marker for cardiomyopathy; and the intermittent bradycardia usually coexists with ventricular tachyarrhythmias of variable severity. Cardiomyopathic patients may have a subtle autonomic dysfunction that predisposes to neurocardiogenic bradycardia.

Reflex-mediated syncopes may occur in specific circumstances. These situational syncopes are common in dogs of all ages but rare in cats. Situational syncope is most common in small, middle- to old-aged dogs; it is often associated with cough caused by tracheal or bronchial disease or advanced mitral valve disease with compression of a main-stem bronchus. In addition to tussive syncope, other situations include deglutition, gag-wretch, emesis, micturition, and defecation. Thus the situation defines the trigger (i.e., tussive syncope, deglutition syncope, emesis syncope, micturition syncope, and defecation syncope). We believe that advanced mitral valve disease in elderly small dogs predisposes to all situational syncopes, as does severe pulmonary hypertension. When the heart rate is documented during situational syncope, it is almost always slow. Far more difficult to document is the systemic blood pressure at the time of syncope; therefore the vasodepressor arm of the reflex is generally overlooked.

The presentation of neurally mediated syncope in affected dogs may not be consistently precipitated by any given situation. Patients can be variably affected so that cough, emesis, exertion-excitement, micturition, and defecation do not cause syncope each and every time.

DIAGNOSING THE CAUSE OF SYNCOPE

The diagnostic goal is to document the heart rhythm at the time of the event. The patient history, physical examination, situational activity, and symptoms that occur during and after the event are crucial to establishing the cause of syncope. Table 158-1 lists the cause and diagnostic associations.

Box 158-1	
Common Causes of Syncope	
Structural Cardiovascular Disease <ul style="list-style-type: none">• Outflow obstruction (pulmonic stenosis, aortic stenosis)• Obstruction to right atrial filling (cardiac tamponade, constrictive pericarditis, tumor)• Pulmonary hypertension• Poor myocardial contractility	Metabolic Disorders <ul style="list-style-type: none">• Hypoglycemia• Endocrine (Addison’s)• Hypoxia• Anemia
Electrical Disease (Extreme Bradycardia or Tachycardia) <ul style="list-style-type: none">• Sick sinus syndrome• Advanced atrioventricular (heart) block• Supraventricular tachyarrhythmias (most common are atrial fibrillation and reentrant tachyarrhythmias)• Ventricular tachyarrhythmias	Neurally Mediated Syncope <ul style="list-style-type: none">• Neurocardiogenic (reflex-mediated)• Situational

General Diagnostic Tests

Routine laboratory tests generally do not identify the cause of syncope, but they should be performed when the history and physical examination are indications. A complete blood count is used to rule out anemia and infection. A serum chemistry profile is used to identify metabolic disorders (evaluate electrolyte abnormalities, blood urea nitrogen, creatinine, and glucose levels). An adrenocorticotrophic hormone stimulation test is indicated in cases of suspected hypoadrenocorticism. Serum thyroxine is appropriate in cases of sinus bradycardia.

Imaging Studies

An echocardiogram with Doppler examination may be useful in patients with a heart murmur and to assess structure and function of the heart. It may also rule out occult pericardial disease, pulmonary hypertension, or intracardiac mass lesions. If a seizure is suspected, a computed tomography scan or magnetic resonance imaging may be indicated.

Testing for Arrhythmias

The only certain way to identify arrhythmias as the cause of syncope is to document the heart rate and rhythm during an episode. Real-time auscultation is useful because it documents the associated rate as fast, slow, or normal.

Table 158-1

Signs Associated With Syncope

Type or Cause Of Syncope	Usual Associations
Classical situational syncope	Coughing, gagging, retching, swallowing, vomiting, micturition, or defecation
High preload in small breed dogs	Exertion-excitement precipitated Loud heart murmur Severe left atrial enlargement ECG: normal or chamber enlargements
Physical exertion in a dog with an aortic or pulmonic stenosis	Consider outflow obstruction May also involve ventricular arrhythmia or neurocardiogenic syncope
Pulmonary hypertension	Heartworm disease, mitral valve disease, severe lung disease, exertional signs, right-sided congestive heart failure
Sick sinus syndrome	Breed: miniature schnauzer, American cocker spaniel ECG: sinoatrial arrest, sinus bradycardia, junctional or ventricular escape beats and brief rhythm, atrial or junctional premature contractions, atrial or junctional tachycardia, and occasionally ventricular premature contractions
Atrial fibrillation	Advanced MR or dilated cardiomyopathy
Ventricular tachycardia	ECG: ventricular tachycardia, particularly cardiomyopathic boxers and Doberman pinschers
Heart block	ECG: bradycardia caused by advanced second- or third-degree AV block

AV, Atrioventricular; ECG: electrocardiogram; MR, mitral regurgitation.

Presumptive diagnosis of the cause of syncope is sometimes legitimate when specific arrhythmias are recorded on a standard ECG rhythm strip in breeds at high risk of syncope from that condition. For example, ventricular tachycardia should be presumed as the likely cause of syncope in Doberman pinschers and boxers when subsequent ECGs contain frequent PVCs (see Table 158-1). Specific clinical disorders or precipitating situations can be highly suggestive of a cause of syncope, but optimally the rhythm during an event should be known. In most cases rhythm disturbances are episodic, in which case a 24- to 48-hour Holter recording or a 5- to 7-day event recording is useful. For longer-term monitoring an implantable continuous-loop ECG recorder can be used. We sometimes issue a chest-press ECG (Veterinary Biolog) that enables the owner to document the heart rhythm associated with infrequent syncope. Humans with reflex-mediated syncope are evaluated by tilt-table, but this examination needs more development in dogs.

TREATMENT

Treatment of syncope varies with the cause and is aimed at managing the underlying disorder. If an arrhythmic etiology is discovered, antiarrhythmic medication or pacemaker therapy is indicated (Table 158-2).

Neurocardiogenic bradycardia and syncope caused by high preload often responds favorably to cardiac unloading therapy. Exertion-excitement-related syncope in elderly small dogs with loud mitral murmurs may be a warning of impending congestive heart failure. Treatment includes a furosemide, an angiotensin-converting enzyme inhibitor, and perhaps spironolactone. Furosemide should be considered even if pulmonary edema is not present on thoracic radiographs. After 1 to 2 weeks adjuvant afterload reduction using amlodipine can be added to the treatment regimen. The addition of digoxin may decrease the numbers of syncope episodes. Although the exact mechanism is unknown, digoxin modulates baroreceptor function and inhibits sympathetic nerve discharge (the trigger for this type of neurally mediated syncope). Digoxin is not indicated in sinus bradycardia or in cases of AV block. The frequency of syncope can be further reduced by client education and the avoidance of instigating situations to whatever extent is practical. Treatment-resistant episodes sometimes respond favorably to sympathomimetic or anticholinergic therapy.

Fight or flight-stimulated neurocardiogenic syncope in boxers, Doberman pinschers, golden retrievers, and dogs undergoing attack training is best "treated" by avoiding the instigating situations. Preventive anticholinergic therapy is recommended only when episodes are predictable (i.e., scheduled exertion that might precipitate an event).

β -Blockade has been recommended for treatment of humans with neurocardiogenic syncope precipitated by sympathetic surge. β -Blockade is effective in some humans. However, this therapy is often ineffective and can be aggravating when bradycardia is the main component of the syndrome.

Syncope in cats is usually the result of a heart rhythm disturbance. Neurally mediated syncope and sick sinus syndrome are rare. In old cats intermittent or sustained heart blocks are the most common arrhythmic causes of

Table 158-2

Treatment of Syncope

Drug	Indication	Maintenance Dosage (mg/kg)	Frequency
Amiodarone (Cordarone)	Ventricular and supraventricular arrhythmias	10* 5*	BID for 1 week (loading) SID (maintenance)
Sotalol	Ventricular and supraventricular arrhythmias	0.5-2 Cat: 10 to 20	BID BID
Mexiletine	Ventricular arrhythmias	5-8	TID
Furosemide	Overt or impending CHF	1-2	BID-TID
ACE inhibitor	Overt or impending CHF		
Enalapril		0.5	SID
Benazepril		0.5	SID
Spironolactone	Overt or impending CHF Electrolyte control	1-2	BID
Digoxin	Atrial fibrillation (control ventricular response rate)	0.005-0.01†	BID
Diltiazem	Atrial fibrillation (control ventricular response rate)	Diltiazem XR (Dilacor) Dog: 3-4 mg/kg Cat: 30-60 mg total dose (start with 30 mg SID) Cardizem CD Cat: 10 mg/kg Cardizem Dog: 0.5-1.5 mg/kg Cat: 7.5 mg total dose	TID BID SID-BID SID TID (titrate dose to effect) BID-TID (titrate dose to effect)
Amlodipine	Afterload reduction	0.3-0.4‡	BID
Pacemaker	Advanced heart block Sick sinus syndrome	Not applicable	
Hyoscyamine sulfate	Sick sinus syndrome	0.003-0.005§	TID
Propantheline bromide	Sick sinus syndrome	0.2-0.5	BID-TID

ACE, Angiotensin-converting enzyme; CHF, congestive heart failure.

*Recommended dosage range in veterinary medicine is testimonial and variable.

†In dogs weighing less than 20 kg.

‡Initiate at 0.1 mg/kg and up-titrate weekly while monitoring blood pressure. Target dosage is 0.4 mg/kg. Target systolic blood pressure is around 110 mm Hg.

Initiate therapy once ACE inhibitor maintenance therapy has been established.

§Consider if positive response to intravenous atropine test (0.044 mg/kg). Pacemaker implantation is the treatment of choice.

Editor's note: Some patients with neurocardiogenic syncope respond (paradoxically) to sympathomimetic drugs such as terbutaline or theophylline.

syncope and episodic weakness. Some cats have a normal ECG during hospital examinations and are often misdiagnosed as having a seizure disorder. In young to middle-aged cats rapid ventricular tachycardia is a common cause of syncope. The majority of these cats have hypertrophic cardiomyopathy. Cats with hypertrophic cardiomyopathy and loud, apical systolic heart murmurs may also experience exertional syncope or presyncope as a result of left ventricular outflow tract obstruction. These patients usually respond favorably to β -blocker treatment. Metabolic causes of syncope are uncommon. Occasionally hypoglycemia can occur as a result of insulin treatment in diabetic cats. Profound anemia can result in exertional syncope or presyncope in cats and dogs.

Systemic Hypertension

REBECCA L. STEPIEN, *Madison, Wisconsin*

ROSEMARY A. HENIK, *Madison, Wisconsin*

Systemic hypertension (pathologic elevation of systemic blood pressure [BP]) is increasingly recognized as a cause of morbidity in pet cats and dogs. Systemic hypertension (HT) usually represents a complication of other systemic diseases in dogs and cats and therefore is classified as *secondary* hypertension. However, in some cases a causative disease is not apparent after careful investigation, and the HT is deemed *primary* or *idiopathic*. Whether primary or secondary, persistent systemic HT indicates a failure of the body's physiologic adaptations to normalize BP in the setting of inappropriate elevation.

OVERVIEW OF SYSTEMIC HYPERTENSION IN THE POPULATION

Persistent elevation of systolic BP to values greater than 160mm Hg is associated with progressive renal injury in dogs, and the severity of renal injury has been correlated to the degree of elevation (Finco, 2004). Potential renal pathologic changes induced by systemic HT include both glomerular and tubulointerstitial changes with resulting ischemia, necrosis, atrophy, and exacerbation of proteinuria. These gradual and additive changes may be difficult to quantify in living animals with preexisting renal disease, but systolic HT (>160mm Hg) at the time of presentation increases the odds of uremic crisis and death in dogs with renal disease (Jacob et al., 2003). Systolic BP higher than 180mm Hg has been associated with ocular injury, including retinal or intraocular hemorrhage; retinal vascular tortuosity; and retinal detachments and retinal degeneration that may cause acute blindness, especially in cats. Neurologic abnormalities, most often intracranial in nature, including seizures, mentation changes, and vestibular signs, have been noted in dogs and cats with HT and are more likely when systolic pressures exceed 180mm Hg. Although variable cardiac hypertrophy has been documented in cats with naturally occurring HT (Henik, Stepien, and Bortnowski, 2004; Nelson et al., 2002; Chetboul et al., 2003) and has been shown to regress with successful antihypertensive therapy (Snyder, Sadek, and Jones, 2001), the degree of hypertrophy has not been shown to correlate with severity of HT. In dogs with experimentally induced HT, hypertrophy and diastolic dysfunction without fibrosis occurred within 12 weeks (Douglas and Tallant, 1991). Although congestive heart failure caused by systemic HT appears to be rare in either species, the onset, development, and clinical repercussions of cardiac changes resulting from sustained HT await further study in cats and dogs with naturally occurring systemic HT.

Systemic HT may be recognized when BP is measured as part of a diagnostic evaluation in animals known to have or suspected of having systemic diseases associated with the development of HT. Alternatively, elevated BP may be detected when clinical signs of HT (typically retinal detachment or intracranial neurologic signs) lead to BP measurement (Table 159-1). Although periodic BP evaluation in healthy patients has been advocated by some authors, the moderate sensitivity (53% to 71%) and specificity (85% to 88%) of oscillometric and Doppler methods to detect systolic BP greater than 160mm Hg in conscious dogs increases the risk of false-positive and false-negative readings (Stepien et al., 2003). However, in cats these concerns may be modulated by the increased prevalence of diseases (chronic renal insufficiency and hyperthyroidism) associated with development of systemic HT in older cats. Because these diseases may have an insidious onset, annual BP screening of apparently healthy older cats may be warranted.

Detection of systemic HT as a complication of systemic disease requires an understanding of the diseases likely to produce systemic HT as a comorbid factor. Hypertension in the general canine population is thought to be approximately 1% to 10% (Bodey and Michell, 1996; Remillard, Ross, and Eddy 1991), and prevalence of HT in the healthy feline population is unknown. In both cases systemic HT is more common in subpopulations affected by particular diseases (Table 159-2). Published prevalence rates are highly variable for many diseases based on the criteria used for diagnosis (i.e., the number used as a "cut off" for normal values), advances in the early recognition of some diseases, and variability in BP measurement techniques.

In cats renal disease is the most likely cause of systemic HT. Renal disease is highly prevalent in the feline population, and HT occurs in approximately 20% to 30% of cats with this disease (Syme et al., 2002). In early studies as many as 86% of hyperthyroid cats had BP above the reference range; but more recent anecdotal evidence suggests that the prevalence rate of HT in hyperthyroid cats is much lower (\approx 10% to 30%), perhaps as a result of increased screening and earlier detection of hyperthyroidism (before hypertensive complications develop). Many elderly cats have both chronic renal insufficiency and hyperthyroidism, complicating analysis of the prevalence of HT in these diseases. The prevalence of HT in cats with diabetes mellitus is poorly documented, but BP screening in diabetic cats is warranted clinically, especially if proteinuria is present.

Numerous studies in dogs support chronic renal disease (especially glomerular disease), hyperadrenocorti-

Table 159-1

Indications for Measurement of Blood Pressure in Dogs and Cats*

Both Species	Dogs: Additional Indications	Cats: Additional Indications
<ul style="list-style-type: none"> • Intraocular hemorrhage • Retinal hemorrhage/detachment • Intracranial neurologic signs • Renal disease • Diabetes mellitus • Left ventricular hypertrophy not associated with outflow obstruction • Use of medications that can raise blood pressure • Sudden decompensation of left-sided cardiac disease 	Both species list plus: <ul style="list-style-type: none"> • Hyperadrenocorticism • Acromegaly • Pheochromocytoma • Primary hyperaldosteronism 	Both species plus: <ul style="list-style-type: none"> • Hyperthyroidism • Left ventricular hypertrophy • Heart murmur

*All cats should have systemic hypertension excluded as a cause of left ventricular hypertrophy before a diagnosis of idiopathic hypertrophic cardiomyopathy is made.

Table 159-2

Diseases Associated With Development of Systemic Hypertension in Dogs and Cats*

Disease	Estimated Prevalence of Systemic Hypertension (if known) (%)	Comment
Dogs		
Renal disease	60-90	Proteinuric animals may be at higher risk.
Hyperadrenocorticism	70-80	Proteinuric animals may be at higher risk.
Diabetes mellitus	25-50	Only small numbers of patients analyzed.
Pheochromocytoma	Unknown	Systemic hypertension may be periodic with catecholamine surges.
Primary hyperaldosteronism	Unknown	
Acromegaly	Unknown	
Use of hypertensive medications	Unknown	Phenylpropanolamine and corticosteroids most frequently implicated.
Cats		
Renal disease	20-65	Early studies documented higher prevalence.
Hyperthyroidism	10-86	Early studies documented higher prevalence.
Diabetes mellitus	Unknown	One study suggested a low prevalence.
Primary hyperaldosteronism	Unknown	
Use of hypertensive medications	Unknown	Corticosteroids are implicated most frequently.

*See text for references.

cism, and diabetes mellitus as the most common diseases associated with secondary systemic HT. Other uncommon endocrine diseases associated with HT in dogs include pheochromocytoma, primary hyperaldosteronism, and acromegaly. The use of hypertensive medications such as phenylpropanolamine or corticosteroids may elevate BP primarily or as an additive effect to a causative disease. Healthy sight hounds may have resting BP values up to 15 mm Hg higher than other breeds of similar size (Bodey and Michell, 1996) and should be assessed accordingly.

DIAGNOSIS OF SYSTEMIC HYPERTENSION

Studies of ease of use, accuracy, and precision of various noninvasive BP measurement systems have been performed

in normal and hypertensive dogs and cats. In general, Doppler methods using a forelimb (radial) cuff are recommended for use in cats. In dogs oscillometric or Doppler methods with radial, metatarsal, or proximal tail cuffs are used. In all cases the patient should be calm and acclimated to the environment and position before measurement. Cuff width chosen should approximate 40% of the circumference of the limb at point of placement, and the limb or tail should be positioned such that the cuff site is at the level of the heart during measurement. Typically six consecutive BP measurements with simultaneous heart rates are recorded. The first measurement and any obviously spurious measurements are discarded, and the remaining values averaged for a representative reading. Careful training of specific personnel in the practice of measuring BP carefully

and recording values consistently is highly recommended. Frequently cuff size is relatively too narrow to effectively occlude the artery, and measured pressure is higher than actual arterial pressure. The opposite occurs if the cuff is relatively too wide. When elevated ABP is identified, some clinicians recommend remeasuring pressure in the opposite limb or alternative site to exclude anatomic factors that may impact arterial occlusion.

Measurements obtained from an initial session should be interpreted in conjunction with the patient's clinical signs or concurrent disease and the observed level of patient agitation at the time of measurement. The recording of simultaneous heart rate is a helpful adjunct in assessing the patient's state of agitation. Either isolated systolic HT or combined systolic and diastolic HT is identified in the majority of hypertensive dogs. For this reason and because noninvasive measurement methods in current use most reliably deliver systolic BP measurements, decisions regarding diagnosis and therapy are usually based on systolic readings.

Studies of human hypertensive patients indicate a progressive increase in risk of end-organ damage as BP increases above normal values. Although antihypertensive therapy is indicated in an individual patient as soon as end-organ damage begins to occur, in veterinary patients the pressure at which an individual begins to sustain end-organ damage is usually unknown. Since recognizable injury to various organ systems has been documented when systolic BP exceeds 160 mm Hg chronically, antihypertensive medications currently are recommended for patients in this group (Brown et al., 2007). It is likely that this current cut-off value will change as more information becomes available.

If elevated BP is documented at a single session and no clinical signs of HT (ocular or neurologic) or obvious target organ injury are present, a repeated measurement should be scheduled, preferably within a week. If elevated BP is confirmed, a detailed diagnostic evaluation to search for a causative disease should be initiated (Box 159-1). If a known causative disease is present, therapy for HT can be started in conjunction with optimal management of

the underlying disorder. If systolic BP is between 160 and 180 mm Hg and no clinical signs of HT are present, BP may be monitored until the diagnostic evaluation is complete. If BP remains elevated and causative disease is found, therapy of the underlying disease (e.g., hyperadrenocorticism) should be initiated, and BP monitored for response to treatment of the underlying disease. If thorough diagnostic evaluation fails to reveal a causative disease, animals with consistently elevated BP should be treated with antihypertensive medications and monitored for development of systemic disease or complications.

THERAPY OF SYSTEMIC HYPERTENSION

Multiple therapeutic options are available to treat the hypertensive veterinary patient. As is the case in humans, many animals need more than one medication to control HT adequately. This is predictable based on neurologic and endocrine control of the cardiovascular system. Mean arterial pressure is controlled by the interaction of systemic vascular resistance and cardiac output. In turn, cardiac output relies on the interaction of the heart rate and stroke volume, a value affected by preload (a reflection of blood volume), afterload, and contractile function. With intricate interplay of the sympathetic and parasympathetic nervous systems, endocrine control of blood volume, and vascular tone modulation through the renin-angiotensin-aldosterone and other systems, the cardiovascular system is capable of at least partially compensating for medication effects.

Thus it is reasonable to assume that better control of BP may be possible if direct vasodilating medications (e.g., amlodipine besylate) are combined with medications that limit the ability of the compensatory mechanisms to adjust to medication-induced changes (e.g., angiotensin-converting enzyme [ACE] inhibitors). For many clinicians the combination of amlodipine plus an ACE inhibitor represents typical therapy for feline HT. In addition, concern has been expressed regarding the possible detrimental effects of using calcium channel blockers as monotherapy. Calcium channel blockers cause preferential vasodilation of afferent renal arterioles and increase intraglomerular pressure in some circumstances. This afferent vasodilation, if combined with inadequate decreases in systemic BP, may actually promote glomerular damage (Brown et al., 1993; Jacob et al., 2003). In theory combining efferent arteriolar dilation associated with ACE inhibitors with the stronger antihypertensive effects of amlodipine or other dihydropyridine calcium channel blockers may provide optimal BP management while conferring some degree of renal protection against progressive injury. Finally, some conditions have recognized indications for specific medications (e.g., ACE inhibitors in proteinuric diseases, sympathetic nervous system blockade in symptomatic pheochromocytoma, aldosterone antagonists in hyperaldosteronism). In these cases indicated medications should form the basis for therapy, with additional medications with different mechanisms of action added as needed. In nonemergent cases (systolic BP less than 200 mm Hg, no evidence of ocular or neurologic signs), at least 7 days should elapse before adding new antihypertensive medications.

Systemic HT in cats (idiopathic or secondary to renal insufficiency or diabetes mellitus) responds well to therapy

Box 159-1

Recommended Diagnostic Testing for Patients With Systemic Hypertension

Dogs

- Funduscopic examination
- Serum chemistries
- Urinalysis
- Urine protein screening
- Hyperadrenocorticism screening
- Adrenocorticotrophic hormone stimulation test
- Dexamethasone suppression test
- Abdominal ultrasound if indicated for additional renal and adrenal evaluation

Cats

- Funduscopic examination
- Serum chemistries
- Urinalysis
- Urine protein screening
- Thyroid screening if appropriate based on age

with amlodipine besylate (0.625 to 1.25 mg/cat q24h orally [PO]), and consistent administration typically results in long-term BP control (Elliott et al., 2001). In addition, early therapy with amlodipine in cats with blindness caused by retinal detachment may allow return of at least partial visual ability (Maggio et al., 2000). In cats with proteinuria addition of an ACE inhibitor to amlodipine therapy may reduce renal protein loss, but an ACE inhibitor alone is unlikely to control HT when used as a monotherapy. ACE inhibitors in common use for hypertensive cats are enalapril maleate (0.25 to 0.5 mg/kg q12-24h PO) and benazepril (0.25 to 0.5 mg/kg q24h PO). Benazepril may be preferred in cats with renal disease because of some hepatic elimination. Cats with controlled HT should be reevaluated at regular intervals to assess BP and renal function. Hypertensive cats with hyperthyroidism may benefit from amlodipine therapy with simultaneous β -blockade (e.g., atenolol, 6.25 to 12.5 mg/cat q12h PO) to help control tachycardia and other cardiovascular effects of thyrotoxicosis. If medical or surgical resolution of the hyperthyroidism occurs, antihypertensive medications can be tentatively reduced or eliminated, and the BP rechecked. Some cats remain hypertensive after resolution of thyrotoxicosis and require chronic antihypertensive therapy, often because of concurrent renal disease.

Canine HT typically is more challenging to control than feline HT. The reason for this disparity is unknown but makes dogs much more like humans, in whom the need for more than one antihypertensive medication to control BP is the norm. The BP effects of antihypertensive medications on BP are additive, but presumably so are the side effects. Ideal antihypertensive therapy would consist of optimal control of the causative disease paired with the minimal number of antihypertensive medications required to control BP to target systolic values of 145 to 160 mm Hg.

When specific abnormalities are identified (e.g., catecholamine excess in pheochromocytoma, excessive aldosterone secretion in primary hyperaldosteronism), targeted medical therapy such as α - and β -blockers or aldosterone antagonists (e.g., spironolactone, 1 to 2 mg/kg q12h PO) is indicated. If systemic HT persists, addition of an ACE inhibitor or amlodipine may be beneficial.

In dogs with renal disease, hyperadrenocorticism, or diabetes mellitus, a standard progressive protocol can be used and results in control of systemic HT in the majority of cases. ACE inhibitors such as enalapril (0.5 mg/kg q12-24h PO) or benazepril (0.5 mg/kg q12-24h PO) are indicated to limit renal protein loss in dogs with proteinuria, and administration usually results in an approximately 10% decrease in systolic BP in these and other patients with renal insufficiency. If systemic HT is mild, this 10% decrease may be sufficient to decrease BP to within an acceptable range. Although twice-daily dosing of an ACE inhibitor may result in more rapid onset of effect than once-daily dosing, it is unclear whether twice-daily dosing is more effective for BP control at steady state. Current recommendations for therapy for both proteinuria and HT are to begin at once-daily dosing and increase to twice-daily dosing if inadequate response is noted.

The calcium channel blocker amlodipine besylate (0.1 to 0.2 mg/kg q12-24h PO) is a direct vasodilator useful in the management of systemic HT of any cause. Amlodipine

appears to cause minimal reflex tachycardia, a side effect of some other direct vasodilators. As is the case with an ACE inhibitor, once-daily dosing is used and increased to maximal doses as needed. Frequency may be increased to twice-daily dosing if response is inadequate. Some animals require higher doses of amlodipine than typically recommended; animals receiving doses above the recommended range should be monitored closely for hypotension, changes in renal function, and other side effects. The long elimination half-life of amlodipine in dogs may require a 1-week follow-up to more fully evaluate the antihypertensive effect.

Apparently refractory or difficult-to-manage systemic HT occurs occasionally in the canine population. In any case of apparently refractory HT, owner understanding and compliance with the dosing schedule should be checked. Ideally BP should be measured approximately 12 hours after steady state is attained; measurement of BP several hours after dosing may underestimate medication effects. Additional diagnostics may be required to identify additional causative factors in animals with more than one predisposing condition (e.g., discovery of hyperadrenocorticism in a patient with diabetes). In cases of truly refractory HT other medications (hydralazine, prazosin, spironolactone, diuretics) can be added to the patient's therapeutic plan. In general, addition of multiple medications based on theoretic benefit should be approached with caution, and all additional medications should be initiated at the low end of the dosing range with close BP and biochemical monitoring. There is a distinct shortage of clinical data supporting the safety and efficacy of multiple-drug regimens in the canine and feline hypertensive population. Additional medications may contribute to hypotension, dehydration with resultant renal dysfunction, and remote side effects such as inappetence or complicate the therapeutic plan for the caregiver without evidence of advantage over simpler routines.

Emergent hypertension with severe end-organ injury (active retinal detachment, intraocular bleeding, progressive central nervous system signs) should be treated in the hospital; amlodipine generally works very well in this setting. Rarely is sodium nitroprusside, hydralazine, or prazosin needed; and in such cases it is reasonable to contact a specialist to discuss therapy.

No clinical studies are available that address the prognosis for survival in cats and dogs affected with hypertension as a primary problem or a complication of systemic disease. Prognosis is likely varied based on the underlying disease, severity of hypertension, and presence and severity of clinical signs. Present therapeutic recommendations are aimed at ameliorating clinical signs and preventing progression of end-organ damage.

CHAPTER 160

Permanent Cardiac Pacing in Dogs

MARK A. OYAMA, *Philadelphia, Pennsylvania*
D. DAVID SISSON, *Corvallis, Oregon*

Artificial pacing (AP) is extremely effective at resolving clinical signs of syncope, lethargy, and exercise intolerance secondary to bradyarrhythmias. The most common cardiac arrhythmias treated by pacing include sinus arrest (sick sinus syndrome), high-grade second- and third-degree (complete) atrioventricular block, and bradycardia associated with persistent atrial standstill. These rhythm disturbance disorders are discussed in more detail in Chapter 158 (also see Rishniw and Thomas, 1999). Temporary pacing is sometimes needed for patients with bradyarrhythmias and is reviewed in Chapter 8. This chapter emphasizes current developments in cardiac pacing in dogs.

In veterinary patients the most common method of permanent AP involves transvenous, single-lead, single-chamber ventricular pacing. This form of AP is performed routinely in academic and private referral hospitals and is associated with improved quality of life and high client satisfaction. Despite the relative ease of placement and satisfactory clinical results, optimal AP requires increasing attention to the growing list of pacemaker capabilities, programming parameters, and potential complications. Since the first veterinary

implantation in the early 1960s (Buchanan, 2003), AP has been the subject of much study. The reader is directed to several excellent reviews regarding the indications, equipment, technique, and practice of AP in veterinary medicine (Moise, 1999; Sisson, 1991; Rishniw and Thomas, 1999; Johnson, Martin, and Henley, 2007; Wess et al., 2006). After briefly reviewing the current method of AP, this update will highlight potential limitations of conventional AP and then introduce technologies that could advance the treatment of symptomatic bradyarrhythmias.

CONVENTIONAL ARTIFICIAL PACING

Conventional transvenous AP typically is accomplished by placing a pacing lead into the right ventricular apex via the jugular vein. The distal tip of the lead is secured into the ventricular endocardial surface, and the proximal end exits the jugular vein and is attached to a battery-powered generator. The vast majority of AP systems implanted in this manner are programmed to both detect and administer electrical impulses at the right ventricular

apex. The usual mode of AP accomplished in this fashion is indicated by the three-letter code VVI, wherein the pacing system performs two functions. The first involves sensing of native cardiac depolarizations in the ventricle, during which time the AP system is quiescent (or inhibited). The second involves delivery of an electrical pacing discharge, following a prescribed time period of no detected native electrical activity. This so-called “demand” pacemaker function prevents periods of asystole and associated clinical signs.

The performance of modern AP systems can be fine-tuned using a wide array of programmable parameters, which, when properly set, allow safe, stable, and long-term treatment (Table 160-1). For example, the pulse duration and amplitude of the pacing discharge can be adjusted to maximize battery life while still ensuring functional depolarization of the ventricle. A number of pacing parameters can be adjusted after surgery via telemetric communication with a portable programming computer. To ensure safe and efficacious pacing, meticulous attention must be given to the proper programming of the pacemaker system parameters. Improper settings can lead to loss of pacing, inappropriate delivery of pacing stimuli, induction of ventricular arrhythmias, congestive heart failure, syncope, and sudden death. In a recent study, inappropriate asynchronous pacing was reported in 42% of dogs receiving AP systems, highlighting the need for follow-up examinations and proper programming (Moise and Estrada, 2002). In humans improper VVI pacing has been associated with sudden death (Zehender et al., 1992). The causative mechanism most likely involves sensing abnormalities, improper timing of pacing discharges, and induction of ventricular fibrillation. In canine AP patients a small but significant percentage of patients (13%)

experience sudden unexpected death, presumably from arrhythmia (Oyama, Sisson, and Lehmkuhl, 2001).

During the first several months following implant, routine electrocardiogram (ECG) examinations are advisable so that improper pacemaker function can be identified and corrected. Many modern pulse generators store their sensing and pacing activity in their resident memory, allowing the examiner to evaluate pacing system behaviors over a long period and thereby facilitate the identification of intermittent pacemaker dysfunction. In cases in which intermittent malfunction is suspected, 24-hour ambulatory ECG (Holter) monitoring can also be performed. Annual or biannual rechecks are advisable to ensure continuation of proper function and to monitor generator battery life.

Most commonly AP is performed in dogs with symptomatic advanced atrioventricular block or sick sinus syndrome. Although the clinical outcome of AP is very favorable, the incidence of complications, both major and minor, is relatively high. In a retrospective study of implantations performed in the early 1990s, 55% of dogs undergoing AP experienced some type of pacemaker-related complication (Oyama et al., 2001). The most commonly reported complication of AP implantation in dogs is dislodgement of the pacing lead from the right ventricle, occurring in 10% of one retrospectively studied canine population. Lead displacement typically results in a loss of sensing and/or pacing. Ventricular tachycardia is sometimes observed if the dislodged lead tip repeatedly impacts the right ventricular endocardium. Lead displacement typically requires a second operative procedure to reposition the lead properly and reestablish normal AP. Other reported AP complications include generator malfunction (6%), infection (5%), and right ventricular perforation by

Table 160-1

Common Programmable Parameters of Modern Artificial Pacing Systems

Parameter	Description
VVI Systems	
Pacing mode	Three-to-five letter code indicating chamber(s) paced, chamber(s) sensed, response, and programmability
Lower rate	Rate the pacemaker paces the heart in the absence of native electrical events; slowest rate the pacemaker allows
Pulse width	Duration of the pacemaker discharge in milliseconds
Amplitude	Intensity of the pacemaker discharge in volts
Sensitivity	Ability of the system to detect native electrical activity in the atria or ventricles
Refractory period	Duration of time following a sensed or paced event that all activity is ignored by the pacemaker
DDD Systems*	
Atrioventricular delay	Time duration between a sensed or paced atrial event and the delivery of a ventricular pacing discharge
Tracking rate	Fastest ventricular pacing rate that can be achieved in response to atrial-sensed events
Rate-Responsive Systems*	
Automatic mode switching	Ability of the pacemaker to automatically switch to a nonrate responsive mode if the atrial-sensed events exceed a programmed rate; helps prevent against excessive tachycardia
Upper rate	Fastest rate the ventricles may be paced in response to sensed atrial activity
Slope	The increase in pacing rate above baseline that occurs at different levels of patient activity
Threshold	Level of sensor activation that is needed to increase heart rate
Reaction time	Time allowed from threshold and the baseline heart rate to achievement of the programmed upper rate
Recovery time	Time allowed from the programmed upper rate to the baseline heart rate following cessation of patient activity

*Parameters found in the specific pacing mode in addition to those found in VVI.

the pacing lead (2%). The rate of complications decreases with increasing experience of the implanting veterinarian. It is our opinion that, as the profession has continued to gain experience, the overall rate of complications associated with transvenous pacemaker implantation has declined. Regardless of the propensity for complications, the remarkable improvement of clinical signs achieved by AP causes most owners (80%) to report a high level of satisfaction with the procedure. The long-term results of AP are encouraging, with nearly half of the patients surviving 3 years after implantation. The presence of severe preexisting heart disease and congestive heart failure negatively influences survival.

Although AP using the VVI mode is the most commonly performed procedure, this modality is accompanied by several important drawbacks. By virtue of its programming and placement within a single ventricular chamber, VVI pacing results in (1) a fixed heart rate, which leads to loss of native heart rate control during times of exercise and rest; (2) an abnormal sequence of cardiac depolarization, evidenced by the wide and bizarre morphology of the QRS complex seen on a surface ECG (Fig. 160-1); and (3) loss of coordinated atrial and ventricular contractions (AV synchrony), which reduces cardiac output and raises atrial pressure as the atria intermittently contract against a closed mitral and tricuspid valve (Fig. 160-2). In humans these deficiencies contribute to the development of “pacemaker syndrome” manifested as fatigue, dizziness, weakness, and on occasion congestive heart failure. Resolution of these signs is accomplished through more advanced and increasingly “physiologic” AP modes that use multiple pacing leads, alternate programming algorithms, or specialized single-lead systems.

ADVANCES IN ARTIFICIAL PACING

Rate-Responsive Ventricular Pacing

With conventional VVI pacing the patient’s paced heart rate is fixed and does not change in response to the cardiovascular demands of the patient. Rate-responsive pacing (VVIR) uses an activity sensor that attempts to

Fig. 160-1 Lead II electrocardiogram from a dog with a single-chamber pacemaker in VVI mode (50 mm/sec). The electrical discharge from the pacing lead (**A**) is immediately followed by a QRS complex representing ventricular depolarization (**B**). Because of the location of the pacing lead within the right ventricular apex, the sequence of ventricular depolarization is altered and delayed, resulting in a QRS complex and T wave with abnormal morphology. Retrograde conduction of the ventricular impulse across the atrioventricular node and into the atrium is suggested by the biphasic P wave seen in the ST segment (**C**).

match the paced heart rate with the patient’s activity. Most commonly the AP systems possess an accelerometer, minute-ventilation sensor, thermometer, gravitation sensor, and/or QT-interval sensor to detect increased patient activity. Once detected, the pacing rate increases to a programmed upper rate limit. In this way the AP system attempts to better mimic the normal heart rate response to activity and more closely resemble the normal physiologic response to exercise. In addition to the upper and lower rates, the operator can program the slope at which the heart rate increases and the activity threshold required to trigger the activity sensors (Fig. 160-3). In humans VVIR pacing improves exercise tolerance and alleviates signs of pacemaker syndrome as compared to VVI pacing. In veterinary medicine patients most likely to benefit from rate-responsive pacing are those with markedly disparate heart rates at rest and during activity. Dogs with a particularly active lifestyle and requirement for exercise are most likely to benefit from rate-responsive pacing systems.

Dual-Lead Dual-Chamber Pacing

Dual-lead dual-chamber pacing (DDD, DDDR) uses a second pacing lead positioned within the right auricular

Fig. 160-2 Lead II ECG from a dog with a single-chamber pacemaker in VVI mode (50 mm/sec). Note that the patient’s native P waves (arrows) and paced QRS complexes are independent of each other and not synchronized. Occasionally the P wave becomes superimposed on the QRS complex or T wave and is not visible. The resultant loss of atrial contribution to cardiac output and contraction of the atria against a closed atrioventricular valve can lead to weakness, dyspnea, and heart failure, which are components of the so-called *pacemaker syndrome*.

Fig. 160-3 Theoretic heart rate versus activity curve of a rate-responsive pacemaker. As patient activity increases, the pacing system increases heart rate to a maximum programmed upper rate. The rate at which the pacemaker increases the heart rate is represented by the slope of the line. The threshold represents the minimum level of activity that causes the pacing system to begin to increase the heart rate.

Fig. 160-4 Lead III electrocardiogram from a dog with a dual-chamber pacemaker (50 mm/sec). The atrial pacing lead delivers an electrical stimulus (**A**) followed by discharge of the ventricular pacing lead (**B**). Dual-chamber pacing preserves synchrony between the atria and ventricles and therefore is more physiologic than single-chamber ventricular pacing.

appendage to sense and pace the atrial chamber. Following atrial depolarization, the DDD system stimulates a timed ventricular depolarization via the lead positioned within the right ventricle (Fig. 160-4). In this way, DDD pacing maintains synchrony between the atrial and ventricular contractions and provides rate responsiveness via sensing the native electrical activity of the right atrium. For these reasons, DDD is the most widely used AP mode in humans. The ideal candidate for DDD pacing is one with advanced atrioventricular block but normal sinus node function. DDD pacing is not ideal in patients suffering from sinus node dysfunction (e.g., sick sinus syndrome) or atrial fibrillation because unregulated detection of rapid atrial depolarizations can lead to excessive ventricular pacing rates (pacemaker-mediated tachycardia). DDD pacing has been described in veterinary patients, but its practice is limited by expense, technical limitations in patients of small size, and complications associated with placement of the atrial lead.

Single-Lead Atrial Synchronous Pacing

Single lead synchronous pacing systems have been developed by including a proximal set of electrodes on the outer surface of the pacing lead that are able to detect atrial electrical activity as it conducts into the blood pool of the right atrial chamber (Fig. 160-5). The atrial electrodes are not in direct contact with the atrial tissue, and atrial depolarizations are “remotely” sensed by the “floating” atrial electrodes. With appropriate programming, detection of an atrial depolarization leads to ventricular pacing after an appropriate interval that is preselected to mimic the normal atrioventricular delay (roughly equivalent to the electrocardiographic PR interval) (Fig. 160-6). This cleverly designed single-lead synchronous VDD system accomplishes the goals of rate responsiveness and maintenance of atrioventricular synchrony without the need for the two pacing leads integral to DDD systems. Ideally this pacing modality is used in patients with advanced atrioventricular block but normal sinus node function. As compared to VVI, VDD pacing is associated with improved hemodynamics and less neurohormonal activation. VDD pacing increases stroke volume and cardiac output and decreases pulmonary capillary wedge pressure, left atrial size, and circulating atrial natriuretic peptide and norepinephrine concentrations in dogs with naturally occurring heart block (Bulmer et al., 2002; Bulmer, 2006).

Fig. 160-5 Left lateral thoracic radiograph from a dog implanted with a single-lead VDD pacemaker. The pacing lead can be seen coursing from the cranial vena cava and into the right heart, with the distal tip of the lead positioned within the right ventricular apex (*white arrowhead*). A set of atrial electrodes is seen positioned within the right atrium (*black arrowhead*), where they are able to sense atrial electrical activity without having to use a separate atrial pacing lead. (Courtesy Dr. B. Bulmer.)

Fig. 160-6 Lead II electrocardiogram from a dog with a single-lead pacemaker in VDD mode. The atrial electrodes detect the patient's native P wave (**A**); following a programmed delay, the pacemaker delivers a ventricular pacing stimulus (**B**), resulting in ventricular depolarization. Note that, because the pacemaker senses native atrial depolarization, the VDD mode allows the patient to control its own heart rate and maintain synchrony between the atrial and ventricular contractions.

Temporary Transthoracic Artificial Pacing

Temporary AP is primarily used for emergency heart rate support in symptomatic patients and acts as a bridge to implantation of a permanent pacing system. Conventional temporary AP involves percutaneous placement of a transvenous pacing lead into the jugular vein and right ventricle (see Chapter 8). Because access to the jugular vein is achieved percutaneously, most cases of transvenous temporary pacing can be accomplished with local anesthesia and manual restraint or mild sedation. Although generally well-tolerated, placement of a transvenous temporary lead requires an experienced operator and can result in infection, hemorrhage, arrhythmias, and cardiac perforation. Temporary AP can also be accomplished in dogs via cutaneous electrodes placed on either side of the chest (DeFrancesco et al., 2003). Compared to temporary

transvenous pacing, transthoracic pacing is noninvasive and can be instituted more quickly in an emergency. A major drawback of transthoracic pacing is pain associated with the delivery of the electrical impulse, necessitating the use of general anesthesia. For this reason we prefer transvenous temporary pacing in most circumstances.

ASSESSING ARTIFICIAL PACING NEEDS IN INDIVIDUAL PATIENTS

The advantages of rate-responsive pacing are self-evident, assuming that the systems function as intended. Simple exercise challenges can be used to assess the sensitivity and performance of rate-responsive AP systems during patient activity. A prospective study involving seven dogs with VVIR systems found a wide range of responses, depending on pacemaker manufacturer and programmed settings, suggesting that treadmill testing can be used to individualize the rate-response parameters of each patient (Ferasin et al., 2005). The value and need for more sophisticated synchronous AP systems are more difficult to determine in veterinary patients. Evidence of a pacemaker syndrome manifests as mild fatigue, dizziness, headaches, and loss of sense of well-being in humans; these symptoms are more difficult to detect in dogs. Without the ability to measure these correlates to these symptoms objectively, it is particularly challenging to identify the veterinary patients that would benefit from VVIR, DDD, or VDD pacing. Although recent attempts to objectively quantify the effects of AP through the use of exercise testing, neurohormone assay, and hemodynamic study show promise, these methods have not yet been refined for clinical use. Inasmuch as atrioventricular sequential pacing has certain hemodynamic advantages, the use of VDD or DDD AP systems should at least be considered for dogs with preexisting valvular or myocardial disease. Future studies are needed to further assess the physiologic

responses to AP and to better identify patients that may benefit from synchronous AP modes.

Assessment and Treatment of Supraventricular Tachyarrhythmias

KATHY N. WRIGHT, *Cincinnati, Ohio*

Once considered relatively benign rhythm disturbances, supraventricular tachyarrhythmias (SVTs) are now known to be both a potential cause and a consequence of structural heart disease. SVTs can induce a variety of clinical signs, including weakness, syncope, and even congestive heart failure (CHF). Sustained or frequently recurrent SVTs may lead to tachycardia-induced cardiomyopathy, indistinguishable from idiopathic dilated cardiomyopathy (DCM) but potentially reversible with effective long-term control of the tachyarrhythmia. SVTs have rarely been known to precipitate sudden death if resultant myocardial ischemia leads to ventricular tachycardia, ventricular fibrillation, or electromechanical dissociation or should the antiarrhythmic drug used to treat an SVT exert a lethal proarrhythmic effect. Insights into SVT mechanisms provided by electrophysiologic studies during the past decade and the ability to cure certain SVTs have improved the diagnosis, treatment, and recognition of complications of these common arrhythmias.

DEFINITIONS

SVTs are rapid rhythms either originating in the atria or using the atria or atrioventricular (AV) junction above the bundle of His as a crucial component of the tachycardia circuit. The term *paroxysmal atrial tachycardia* was used generically by some cardiologists to mean SVT. This general term has become outdated as we learn the multiple mechanisms that are responsible for SVTs. One useful classification scheme with diagnostic and therapeutic applications broadly divides SVTs into atrial or junctional tachyarrhythmias (Wathen et al., 1993). Atrial tachyarrhythmias are SVTs using atrial tissue alone for initiation and maintenance of the arrhythmia. Examples include automatic atrial tachycardia, atrial flutter, and atrial fibrillation. Junctional tachyarrhythmias are SVTs that require the AV junction as an essential component of the initiation or maintenance of the tachycardia; the atrium may or may not be needed. Physiologic sinus tachycardia is in a unique class by itself, not included as a form of SVT.

ASSESSMENT OF SUPRAVENTRICULAR TACHYARRHYTHMIAS

Clues From the History and Physical Examination

History and signalment can provide useful initial information in determining the mechanism of SVTs. The physical examination should include careful evaluation for underlying structural heart disease and heart failure. A clinician should strongly suspect the presence of an accessory AV pathway and AV reciprocating tachycardia or automatic atrial tachycardia in young to middle-aged animals that present with rapid, narrow QRS complex tachycardia without apparent structural heart disease. Based on what is known about humans with similar clinical histories, AV nodal reentrant tachycardia and AV reciprocating tachycardia are the most common SVTs in this group. Animals with DCM and SVT may have SVT resulting from DCM, or, more commonly than previously recognized, DCM resulting from sustained SVT. Often reassessment of the structural heart disease after weeks to months of strict arrhythmia control is the only reasonable means of determining which disease process came first. If the structural heart disease involves primarily atrial dilation, intraatrial reentrant tachycardia, automatic atrial tachycardia, atrial flutter, and atrial fibrillation should be carefully considered.

Surface Electrocardiographic Features

A logical, mechanistic-based approach to the surface electrocardiogram is necessary when one evaluates SVTs. SVTs characteristically exhibit narrow QRS complexes. However, in rare cases a bundle branch block (preexistent or tachycardia-dependent) or conduction from atria to ventricles over an accessory AV pathway produces a wide QRS complex tachyarrhythmia that is supraventricular in origin. However, it is emphasized that the vast majority of tachyarrhythmias with wide QRS complexes are ventricular tachyarrhythmias, not aberrantly conducted SVTs.

Once narrow QRS complexes occurring at a rapid rate have been identified, one must decide whether the QRS

complexes occur in a regular, regularly irregular, or irregularly irregular pattern. Atrial fibrillation is classically irregularly irregular. Other commonly encountered SVTs have regular patterns, although atrial tachycardias and atrial flutter may be conducted irregularly across the AV node, particularly after administration of a drug that blocks AV conduction. Variable degrees of AV block during an atrial tachyarrhythmia produce irregularity in the occurrence of QRS complexes, but the ventricular response may still have a pattern (i.e., it is regularly irregular). Electrical alternans is not uncommon in dogs with SVTs, and this may help the clinician distinguish the rhythm from a simple sinus tachycardia or a ventricular rhythm disturbance.

Identification of P' waves* or flutter (F) waves is the next important step in assessing the tachyarrhythmia; however, P' or F waves may be very hard to identify during a rapid SVT. This task is made more difficult when one examines only one or two limb leads. Instead, all possible leads should be run at both normal and maximal sensitivities. P' waves are often more easily identified in precordial (chest) leads than in standard limb leads. If an electrocardiograph is not equipped for precordial leads or if P waves remain obscure, the right and left arm (forelimb) electrodes of the standard electrocardiograph can be placed in various positions along the sternal borders of the chest wall (Lewis leads) while monitoring the "lead I" channel to better demonstrate atrial activity. Esophageal leads are also valuable, but lack of patient cooperation limits their use.

The presence or absence of visible P' waves, P' wave morphology, and the relationship of a P' wave to the preceding QRS complex all are helpful in SVT diagnosis (Fig. 161-1). The absence of visible P' waves during a regular SVT despite use of all of the tactics previously discussed is suggestive of typical AV nodal reentrant tachycardia, during which atrial and ventricular activation occur simultaneously. If the P' wave is closer to the preceding QRS complex than to the subsequent QRS complex so that the RP' interval is less than or equal to 50% of the RR interval, the SVT is classified as a short RP' SVT. On the other hand, if the P' wave is closer to the subsequent QRS complex with the RP' interval more than 50% of the RR interval, the SVT is known as a long RP' SVT. Fig. 161-1 and Table 161-1 review the electrocardiographic characteristics and mechanisms of the more common SVTs.

Initiation and termination of the tachyarrhythmia are very important diagnostic features. Sudden onset and offset of SVT without gradual rate acceleration and deceleration, respectively, are most characteristic of reentrant SVTs. Automatic SVTs (i.e., from discrete ectopic foci) typically exhibit a "warm-up" (rate acceleration on initiation) and "cool-down" (rate deceleration before termination) period. If a ventricular premature complex successfully terminates an SVT, it is almost certainly a junctional tachyarrhythmia. In cases of atrial flutter, sudden changes in conduction can lead to halving or doubling of the ventricular rate (e.g., a conduction sequence of flutter waves: QRS complexes changing from 1:1 to 2:1 or from 4:1 to 2:1).

*P' waves indicate atrial depolarization that does not originate in the sinoatrial node.

Electrophysiologic Testing

Within the past 20 years in human cardiology, electrophysiologic testing with the use of percutaneously placed multipolar catheters has become commonplace. This valuable tool is available at certain veterinary referral centers and has been an important addition in both the diagnosis and the treatment of particular SVTs. Catheters are advanced to strategic locations in the heart through accessed veins (and occasionally arteries) for pacing and recording. The response of a patient's SVT to programmed electrical stimulation, the sequence of atrial activation, and the location of the His bundle potential during the SVT are used to diagnose its mechanism and map its location.

THERAPY FOR SUPRAVENTRICULAR TACHYARRHYTHMIAS

Acute Management

Division of SVTs into atrial and junctional tachyarrhythmias has important implications for management (Wathen et al., 1993). Junctional tachyarrhythmias may be treated successfully with single-agent therapy directed at any essential component of the circuit. On the other hand, successful management of atrial tachyarrhythmias in terms of gaining both rate and rhythm control requires "dual therapy." One drug is used initially to slow AV nodal conduction; a second drug is used to terminate the atrial tachyarrhythmia itself. The site or sites of antiarrhythmic drug actions are shown in Fig. 161-2.

Vagal maneuvers lasting no more than 5 seconds (ocular pressure, gag reflex, single carotid sinus massage) may be helpful both diagnostically and therapeutically. These maneuvers may increase vagal tone, primarily slowing sinus nodal discharge and prolonging AV nodal conduction time and refractoriness. If an SVT abruptly terminates in response to a vagal maneuver, AV nodal reentrant tachycardia, orthodromic AV reciprocating tachycardia, or sinus nodal reentrant tachycardia is most probable. Unfortunately even SVTs using the sinus or AV nodes as essential circuit components typically fail to terminate with any vagal maneuver. Therefore the lack of response to a vagal maneuver should not be used to rule out an AV nodal-dependent SVT. Rare complications such as ventricular fibrillation may result, particularly from aggressive vagal maneuvers; thus careful electrocardiographic monitoring during the procedure is essential.

Intravenous antiarrhythmic drug therapy may be used to treat a rapid SVT causing hemodynamic compromise and often results in a "revealing" of the underlying mechanism. Hemodynamic (blood pressure) and electrocardiographic monitoring are important whenever one treats SVTs with intravenous agents. Diltiazem (Cardizem, Hoechst Marion Roussel; 0.125 to 0.35 mg/kg intravenously [IV]) comes in a parenteral formulation and is used widely in both human and small animal patients. Diltiazem rapidly slows AV nodal conduction and prolongs AV nodal refractoriness, making it ideal for slowing the ventricular response to rapid atrial tachyarrhythmias and for terminating junctional tachyarrhythmias (except for automatic junctional tachycardia). In cases of intraatrial tachycardia or atrial

Fig. 161-1 Illustration of the mechanisms and characteristic electrocardiographic features of the most common supraventricular tachyarrhythmias. *AP*, Accessory pathway; *AV*, atrioventricular; *ECG*, electrocardiogram; *LAF*, left anterior fascicle; *LBB*, left bundle branch; *LPF*, left posterior fascicle; *RBB*, right bundle branch; *SA*, sinoatrial.

flutter, the consequences of diltiazem therapy are mainly on rate control, although occasionally there is conversion to sinus rhythm. The value of AV nodal block is not only therapeutic but also diagnostic since junctional reentrant tachyarrhythmias should not be associated with independent (blocked) P' or F-waves; conversely these are often observed following diltiazem in cases of intraatrial tachycardia or atrial flutter. Since diltiazem causes negative inotropic effects, cautious use is called for in the setting of left ventricular dysfunction. However, human clinical studies support its effective and safe use in patients with class III

and IV heart failure and rapid SVTs (Heywood et al., 1991; Goldenberg et al., 1994). I have used intravenous diltiazem in dogs with DCM and in dogs with severe tachycardia-induced cardiomyopathy secondary to an incessant SVT that present with rapid, hemodynamically compromising SVT (often atrial fibrillation) after initial treatment with parenteral furosemide if CHF is present. Diltiazem is as effective and appears to have far fewer adverse effects than parenteral verapamil.

Adenosine (Adenocard, Fujisawa USA) is another parenteral antiarrhythmic drug that slows AV nodal conduction

Fig. 161-2 Sites of action of anti-arrhythmic drugs, highlighting their use for specific supraventricular tachyarrhythmias. SA, Sinoatrial; AV, atrioventricular.

Table 161-1

Typical Electrocardiographic Characteristics of Supraventricular Tachyarrhythmias

SVT Mechanism	Visible P' Waves	P' Wave Morphology	RP' Interval (vs. RR Interval)	Initiation/Termination	Response to AVB
Atrial					
SNRT	Yes	Same as sinus P	Long	Abrupt onset/offset at SVT rate	SVT continues
AAT	Yes	Variable, differs from sinus P	Often long, but varies with SVT rate	Gradual rate/acceleration	SVT continues
IART	Yes	Variable, differs from sinus P	Often long, but varies with SVT rate	Abrupt onset/offset at SVT rate	SVT continues
Atrial flutter	Flutter (F) waves	Identical saw-toothed F waves	Not applicable	Abrupt onset/offset at SVT rate	SVT continues
Atrial fibrillation	No; fibrillation (f) waves may be seen	Not seen	Not applicable	Abrupt onset/offset at SVT rate (often incessant)	SVT continues
Junctional					
Common AV nodal reentrant tachycardia	Generally no; may be seen as pseudo-S wave in II, III, aVF	Retrograde (if seen): (–) in II, III, aVF	Short	Abrupt onset/offset at SVT rate; critical PR prolongation to initiate	SVT terminates
OAVRT	Yes; within the ST-T segment	Retrograde: (–) in II, III, aVF	Typically short	Abrupt onset/offset	SVT terminates
AJT	Generally yes; AV dissociation common	Variable	Variable	Gradual rate acceleration/deceleration	SVT continues with AV dissociation

AAT, Automatic atrial tachycardia; AJT, automatic junctional tachycardia; AV, atrioventricular; AVB, atrioventricular block; IART, intraatrial reentrant tachycardia; OAVRT, orthodromic atrioventricular reciprocating tachycardia; SNRT, sinus nodal reentrant tachycardia; SVT, supraventricular tachyarrhythmia.

in humans. It must be administered as a rapid intravenous bolus, ideally through a central vein. Although adenosine is the drug of choice in humans for terminating a wide complex SVT and distinguishing this tachyarrhythmia from ventricular tachycardia, this agent has not been effective in dogs. Adenosine doses up to 2 mg/kg do not slow AV nodal conduction in dogs. In a small number of cases that I have treated, rapid doses of 0.5 mg/kg

intravenously have failed to terminate junctional SVTs, which would consistently terminate in a person at one third of that dosage.

An ultrashort-acting, selective β_1 -blocker, esmolol (Brevibloc, Ohmeda), at 0.5 mg/kg intravenously over 1 minute has been used to slow AV nodal conduction and interrupt certain SVTs. Because its half-life is so brief compared to the longer-acting intravenous propranolol, esmolol

is the preferred parenteral β -blocker because adverse effects such as negative inotropy are also short-lived. Nonetheless it should be used cautiously in animals with ventricular dysfunction. Esmolol appears less effective than parenteral diltiazem in terminating canine junctional SVTs and has become my second choice of intravenous AV nodal-blocking drugs. Both diltiazem and esmolol can be used in cats.

Procainamide is a class IA antiarrhythmic available in a parenteral formulation (Pronestyl, Elkins-Sinn) that prolongs the refractory periods of atrial and ventricular myocardium, retrograde AV nodal pathways, and accessory AV pathways. Dosages of 6 to 8 mg/kg intravenously over 3 minutes or 6 to 20 mg/kg intramuscularly have been successful in terminating or "converting" atrial tachyarrhythmias (after drugs to slow AV nodal conduction have been administered). When given immediately after induction of atrial fibrillation or flutter in dogs with "lone" atrial fibrillation, parenteral procainamide may be effective in converting the rhythm to sinus. This drug also has efficacy in acute and chronic management of AV reciprocating tachycardia in dogs. There is far less experience with parenteral procainamide in cats; however, I have used it cautiously and at a reduced dosage (1 to 3 mg/kg IV over 3 to 5 minutes). The adverse effects include hypotension with rapid intravenous administration and gastrointestinal upset. Myocardial contractility is minimally impaired except at higher doses (although the drug can cause vasodilation); therefore procainamide can be used in animals with left ventricular dysfunction.

Lidocaine generally is used for control of ventricular arrhythmias but has some efficacy in the treatment of atrial fibrillation of acute onset in dogs. The role of lidocaine generally is reserved for dogs in which the induction of the atrial arrhythmia is witnessed and the mechanism is related to elevated vagal tone.

Chronic Antiarrhythmic Drug Therapy

Chronic antiarrhythmic drug therapy for atrial tachyarrhythmias may involve dual therapy to control ventricular rate response and suppress the rhythm disturbance (see Acute Management Therapy for SVTs earlier in the chapter) or combination therapy to simply slow the ventricular response rate. This latter approach is often taken in dogs or cats with *persistent atrial fibrillation* and *severe structural heart disease*.

The canine patient with an atrial tachyarrhythmia and CHF is placed on digoxin (Lanoxin, Glaxo Wellcome; Cardoxin, Evsco Pharmaceuticals) at 0.005 to 0.01 mg/kg orally every 12 hours (dogs). In cats a lower dosage of 0.0312 mg orally every 24 to 48 hours is used. Digoxin represents the initial AV nodal-blocking drug in small animal patients with atrial fibrillation and CHF, except for the cat with hypertrophic cardiomyopathy and atrial tachyarrhythmias in which atenolol or diltiazem are considered the drugs of choice. Generally the ventricular response rate to atrial fibrillation is slowed insufficiently with digoxin monotherapy.

Adding a *second* AV nodal-blocking agent to digoxin generally produces the targeted ventricular response. The choice is between an oral calcium channel blocker and a β -blocker. There are theoretic reasons for supporting either choice. I prefer diltiazem at 0.5 to 1.5 mg/kg orally

every 8 hours (dogs) and atenolol typically at 6.25 mg orally every 12 to 24 hours (cats). Dogs in CHF subjectively appear to tolerate diltiazem better than the dose of β -blocker required to achieve ventricular rate control. The vasodilator properties of calcium channel blockers may partially offset their negative inotropic effects in the failing heart (Falk, 1996). Also, in a small percentage of cases diltiazem has converted an atrial tachyarrhythmia (presumed to be caused by triggered activity) to sinus rhythm. If inadequate heart rate control is achieved with digoxin and diltiazem, a small dose of atenolol or another β -blocker can be added to the antiarrhythmic regimen. Since many of the dogs are also in CHF, it is likely that a β -blocker (such as carvedilol) may later be prescribed for cardioprotection once CHF is stabilized. This type of triple therapy often results in good ventricular rate control.

Oral procainamide (Pronestyl, 10 to 20 mg/kg orally [PO] q4 to 6h [dogs] and 3 to 8 mg/kg PO every 6 to 8 hours [cats] has been used as one agent in dual-therapy regimens to suppress or convert atrial tachyarrhythmias and as single-agent therapy for treatment of junctional tachyarrhythmias. Higher dosages (up to 40 mg/kg PO q6h) have been required for controlling junctional SVTs in some dogs. Gastrointestinal side effects and proarrhythmic concerns (particularly in animals with structural heart disease) are the major factors limiting chronic procainamide use in small animals.

Sotalol (Betapace, Berlex Laboratories, 1 to 2 mg/kg PO q12h) is proving to be effective in both dogs and cats with certain SVTs. Sotalol combines both nonspecific β -blockade with class III antiarrhythmic activity (which prolongs repolarization). Because of this dual activity, sotalol can be used as a single agent in atrial or junctional tachyarrhythmias. Its negative inotropic effects are partially offset by the increased time for calcium entry (Antonaccio and Gomoll, 1990).

Other antiarrhythmic drugs currently under investigation for management of atrial and junctional SVTs in dogs include amiodarone (Cordarone, Wyeth-Ayerst) with the widest spectrum of antiarrhythmic actions and propafenone (Rhythmol, Reliant Pharmaceuticals). Clinicians should consult with a cardiac specialist before using these long-term for control of SVTs.

Nonpharmacologic Therapy

A few veterinary referral centers offer the possibility of curing rather than simply controlling certain SVTs. Transvenous catheter ablation with the use of radiofrequency energy has revolutionized the treatment of SVTs in humans. This procedure follows the mapping of an SVT circuit using multiple electrode catheters. A specialized catheter with a 4- to 5-mm distal-tip electrode is positioned at a critical site within the circuit; and radiofrequency energy is delivered through the distal electrode, causing thermal destruction of a small volume of tissue sufficient to cause interruption of the tachyarrhythmia. This technique has been used with great success in humans, and I have used it in over 40 canine cases.

Management of atrial fibrillation in dogs typically involves simple rate control. However, some centers use synchronized, biphasic cardioversion for rhythm control

back to sinus rhythm. This approach is discussed more fully in Chapter 164.

CHAPTER 162

Ventricular Arrhythmias in Dogs

N. SYDNEY MOÏSE, *Ithaca, New York*
 ANNA R.M. GELZER, *Ithaca, New York*
 MARC S. KRAUS, *Ithaca, New York*

The treatment of ventricular arrhythmias (VAs) has dramatically changed over the last 30 years in human medicine. Reading this literature and more critically evaluating our standard of care in dogs also has altered our approach to the management of VAs. Decades ago recommendations for the treatment of VAs revolved around the number of premature complexes identified by routine electrocardiography, but today treatment is reserved for VAs that are judged to be truly dangerous. Furthermore, the success or failure of long-term treatment is more critically studied by 24-hour ambulatory electrocardiograph (ECG) monitoring (Holter monitoring). In this chapter the following topics are addressed in practical terms and in light of the medications most available to practitioners:

1. When should VAs be treated?
2. What are the most common diseases or circumstances that demand treatment?
3. What determines route of administration, and what medications should be selected?
4. How should the VA be monitored during therapy?

WHEN VENTRICULAR ARRHYTHMIAS SHOULD BE TREATED

VAs should be treated when they result in clinical signs or tachycardiomyopathy or harbor the risk of death. Hemodynamic consequences of VAs that cause clinical signs are related to hypotension. Sustained hypotension causes weakness, lethargy, exercise intolerance, and, if severe and prolonged, syncope. The development of low systemic blood pressure that persists long enough to result in clinical signs is primarily related to ventricular tachycardia (VT) that is rapid and prolonged (sustained) and not to single ventricular premature complexes. It is possible that the latter can lead to R-on-T phenomenon

(i.e., when such beats fall within the vulnerable period of the T wave). Although such timing of a premature complex can induce ventricular fibrillation (VF), how frequently this occurs in the dog has not been ascertained. Thus the criterion to define the R-on-T interval that requires treatment in the dog is unknown. Polymorphic VAs also traditionally have been viewed as more ominous than monomorphic VAs; however, this is not necessarily true. Boxers with arrhythmogenic right ventricular cardiomyopathy (ARVC) have monomorphic VT 85% of the time, and their risk of sudden death is high. Older dogs with mitral regurgitation can have single ventricular premature complexes that are polymorphic and for which the frequency of sudden death is low. In contrast, Doberman pinschers with dilated cardiomyopathy (DCM) do have polymorphic VT and a high incidence of sudden death. Therefore the assessment of risk depends on the incorporation of multiple factors for each patient. It should be emphasized in this appraisal that underlying cardiac disease must be considered in addition to the type of VA present. Animals can tolerate sustained and rapid VT for more prolonged periods if they have adequate myocardial function and are capable of compensating (e.g., baroreceptor reflex) for the VT. Therefore, when there is underlying myocardial failure (e.g., DCM, ARVC, substantial AV valve regurgitation) or anesthetic depression of heart function, the need to suppress the VT is more important. However, because of additional physiologic issues such as renal perfusion and concurrent drug medication, treatment is also more challenging. It is important to note that, when a tachyarrhythmia persists, both structural and electrical remodeling can develop. These are detrimental electrically and can induce myocardial failure. This has been shown both experimentally and clinically in the dog (i.e., a dog that initially only has a tachyarrhythmia will develop myocardial failure if the rapid rate is not controlled). The myocardial failure can be permanent if the arrhythmia persists for a number of weeks or even days if the rate is very fast. Thus one of the major determinants of risk and need to treat rests in the rate of the arrhythmia. The faster and more sustained the VA, the more aggressive the treatment must be.

DISEASES AND CIRCUMSTANCES THAT DEMAND TREATMENT

By examining the natural history of a disease or the circumstances that are associated with VA, those that most often result in clinical signs or sudden death can be identified. Likely the two most common diseases that demand treatment for VT are ARVC in boxers and DCM in Doberman pinschers (and other afflicted breeds). Another breed with sudden death related to VT is the German shepherd. The other most common circumstances that cause VT are traumatic myocarditis, myocarditis, gastric torsion/volvulus, and splenic disease.

The VT identified in boxers is most frequently rapid (rates exceed 250 beats/min); monomorphic; and of a left bundle branch block pattern with an upright orientation in leads II and III and a VF. Holter recordings have documented that often the VT that causes clinical signs occurs when dogs are excited or exercising. The latter circum-

stances, which are associated with increases in sympathetic tone, are often the triggers for the VT. Controlling the triggers of arrhythmias can be as important in treatment as therapy to disrupt the substrate or mechanism of the arrhythmia. The mechanism of the VT in boxers is unknown. However, the origin of the VT, based on the morphology and the location of the pathology, is from the right ventricle. Recent studies raise the question of disruption of the intercalated disk proteins in affected boxers that could be an arrhythmogenic substrate (Oxford et al., 2007). Boxers with polymorphic VA often have heart failure, although it is common to observe rapid monomorphic VT in boxers with syncope alone (Kraus et al., 2002). In addition, Holter recordings of syncopal boxers have shown that, in addition to the VT, some dogs have sinus pauses of greater than 8 seconds that are responsible for the clinical signs. (This may represent a neurally mediated bradycardia as part of a neurocardiogenic reflex-mediated syncope). Thus treatment must be tailored to both arrhythmias. Studies are not available to prove that treatment of the VT in boxers actually decreases the risk of death, although some work does support the use of certain drugs for the antiarrhythmic effect. A drug may decrease the frequency of an arrhythmia, but this does not ensure that it will prevent sudden death.

Doberman pinschers with VA demanding treatment almost always have concurrent severe myocardial failure as a result of DCM. This is in contrast to the boxer, in which the echocardiogram often is normal. The polymorphic VT documented in Doberman pinschers may not be the cause of death since bradyarrhythmias have also been documented as another fatal rhythm. Because these dogs are usually on numerous medications and their hemodynamic status is more fragile, the negative inotropic effect of the antiarrhythmic drug must be considered. Most ventricular arrhythmias are affected markedly by elevations in sympathetic tone and circulating catecholamines; thus antiarrhythmics are often combined with β -adrenergic blockers (e.g., mexiletine plus atenolol) or adrenergic blockade as a component of the specific prescribed drug (sotalol, amiodarone). In the Doberman pinscher with DCM, titrating the dosage to have an appropriate antiarrhythmic effect with the least negative inotropic consequence is difficult. In general the comments here apply to other breeds afflicted with DCM.

In the German shepherd, an inherited (major gene is dominant) disease resulting in VA has been characterized by a rapid (>300 beats/min) polymorphic VT with occasional monomorphic VT. Myocardial structure and function appear normal as judged by echocardiography. Sudden death occurs in about 15% of affected dogs and in about 50% of dogs affected with more than 10 runs of rapid VT per 24 hours as determined by Holter monitoring. Death occurs usually between 15 and 52 weeks of age, although younger and older dogs have been reported to die. Most frequently, however, if a dog survives beyond 2 years of age, the risk of death is negligible. Triggered activity caused by early and delayed afterdepolarizations is hypothesized to initiate the VT, although the mechanism for sustained VT and deterioration to VF is unknown. The VT does degenerate into VF as the final, fatal rhythm. The autonomic nervous system plays an important role

in the generation of the VA and the sudden death. Death is associated with sleep, exercise, and excitement shortly after sleep and with early morning excitement. In addition, VT is induced with certain anesthetics or analgesics (e.g., narcotics) that increased vagal tone, resulting in a slowing of the heart rate and exaggeration of sinus arrhythmia. Narcotics can be used in these dogs as long as the dogs also are given anticholinergics to avoid bradycardia. Although the component of the bradycardia is stressed in these dogs, many of the younger affected German shepherds have VA without a slow sinus rate.

Dogs with supposedly noninherited disorders do develop VAs. Some of the most severe VTs can occur in cases of myocarditis (see Chapter 177). Myocarditis does not mean an infectious process necessarily but inflammation. With the advent of markers of leakage proteins from myocytes such as troponin, the identification of myocarditis is more likely. Such patients can have VT that demands emergency care or rhythms in which oral treatment suffice. Controversy exists with regard to the management of dogs with traumatic myocarditis, gastric torsion and volvulus, and splenic disease. In these cases VAs are common, but rhythms that are potentially fatal develop uncommonly. However, because treatment risk usually is low and the treatment is short term and frequently effective, many clinicians prefer to treat the VT in these situations. However, most of the time treatment for traumatic myocarditis is not necessary unless the rate of the VT is greater than 160 to 180 beats/min or the impact on blood pressure is significant. With these diseases underlying insults are responsible for the arrhythmias, including the sympathetic nervous system, myocardial hypoxia or ischemia, decreased coronary perfusion, elevated circulating cytokines, and electrolyte shifts. Dogs with splenic masses often have VAs; these are most often benign and resolve with splenectomy. Of course the list of diseases and circumstances associated with VAs is extensive, but in general these principles are applicable.

DETERMINANTS OF ROUTE, MEDICATION, AND TREATMENT DOSAGE

At first it may seem obvious how one determines if intravenous medication is required; however, this is not always true because the wishes of the owner may not permit hospitalization. Dogs with VT and severe systemic hypotension leading them to a moribund, weak, or repeatedly collapsing state require intravenous treatment with the goal of conversion to sinus rhythm or slowing of the ectopic rate. Sometimes dogs in distress may be cardioverted if synchronization with the R wave is possible to avoid shocking on the T wave (see Chapter 164). Regardless of the type of VT or underlying disease or mechanism, lidocaine is the most common drug given intravenously for the treatment of VT in dogs today. The most common sequence of events is to administer one or several boluses of lidocaine at 1 to 2 mg/kg intravenously and follow this with a constant-rate infusion (CRI) of lidocaine at 40 to 80 mcg/kg/minute. Most frequently CRI dosages approximating 50 to 60 mcg/kg/minute are required to ensure effectiveness. Caution should be used if the total bolus

dosage approaches 6 mg/kg over a 15- to 30-minute period. Toxicity is recognized as twitching or seizures. Because the half-life of lidocaine is short, the side effects dissipate rapidly; but intravenous diazepam might be required. The most common reason for lidocaine toxicity is miscalculation of the dose in terms of decimal point location. Consequently clear written instructions with sample doses for the size of the animal are ideal for checking calculations in the emergency situation. Although lidocaine is the most commonly used drug, some prefer to use procainamide intravenously as a bolus (10 to 15 mg/kg slowly) followed by a CRI (25 to 50 mcg/kg/minute). This drug is uncommonly used orally but still remains as a possible drug for critical VT. Bolus treatment must be delivered with a slower push than lidocaine because more problems can develop with systemic hypotension (although lidocaine doses produce a momentary drop in systemic blood pressure, even in dogs with normal myocardial function).

Because lidocaine has multiple antiarrhythmic mechanisms, it can be effective regardless of disease or circumstance. However, when lidocaine is ineffective, understanding the reasons for failure is important, and alternate medications are needed. Sometimes the reason for a lack of response is that the dose used is too low; thus up-titration is important to eliminate this as an explanation for failure. The antiarrhythmic effects of lidocaine are hindered in the presence of hypokalemia or acid-base imbalance. After these examinations a trial with procainamide is logical. Other drugs can be tried as well, but availability is a major concern. When a drug is selected to treat VT, whether intravenously or orally, and the arrhythmia persists, the diagnosis of the rhythm may be incorrect. Although less frequent, wide QRS supra VT should be considered, as with atrial fibrillation with right bundle branch block. If additional antiarrhythmic drugs are not available for intravenous trial, oral medication and hemodynamic support can be given. Sotalol given orally in such situations has converted dangerous VT in several hours when usual intravenous medications failed. Some clinicians have had success with a slow bolus of amiodarone (5 mg/kg intravenously [IV] over 10 minutes). Finally some VT rhythms are *malignant* and will not terminate or slow. This happens with severe myocarditis, myocardial infarction, or myocardial neoplasia.

Oral medication is used when the VT is not immediately life threatening. The definition of life threatening is determined by both the type of VT and the hemodynamic response of the dog. Some dogs appear undisturbed by a rapid VT, particularly if they have preserved myocardial function and the VT is intermittent. To treat with oral medication usually suffices; however, there are management issues that are critical to knowing the effectiveness of the drug and the dosage selected (see following section). Other dogs may be presented with a history of syncope with the cause suspected to be intermittent VT based on ECG and Holter monitoring. The most commonly used oral drugs given for the treatment of VA are sotalol (2 to 2.5 mg/kg BID), mexiletine (4 to 8 mg/kg TID) combined with atenolol (0.5 to 1 mg/kg BID), or amiodarone. Amiodarone is commonly used in human medicine; however, thus far in the treatment of dogs with VT the published data have emphasized the problems (hepatotoxicity, thyroid

dysfunction), with little evidence of effectiveness against the VT. It is vital to comment on the doses given. These are regarded as *usual* and not exact for a particular patient. Antiarrhythmic drugs and adrenergic blockers must be titrated to effect and with the intent to avoid side effects.

MONITORING TREATMENT OF VENTRICULAR ARRHYTHMIAS

When VT is treated in the intensive care situation with constant ECG monitoring, effective intravenous treatment is identified by conversion to a sinus rhythm. Still, critical evaluation is required if the VT occurs in intermittent runs because the "conversion" may occur simply by chance. With the advent of greater digital storage capacity on computers, electronic ECGs that continuously record the electrocardiogram of a critical patient can be evaluated effectively instead of the "by chance" paper recording. Selected electronic ECG systems currently available can store 1 or more hours of data at a time and then be reset. When dogs are treated by the intravenous route, a positive response to bolus therapy should be seen within minutes and maintained during CRI. If such treatment is given and no effect is documented, the medication plan should be reconsidered. After stabilization of the dog with intravenous treatment, transition to oral medication is initiated if deemed necessary. This transition is started with one to three oral medication doses before stopping the CRI. There is a crossover time when either excessive medication may cause side effects or too little permits the arrhythmia to return. It is important to note that, just because a drug is effective intravenously, it does not mean that it will be effective given orally or that a drug with a similar mechanism action will be effective. It is not uncommon to have a dog treated with lidocaine in the intensive care unit and then switched to sotalol orally with positive effect.

To know if a drug is having (1) no effect, (2) an antiarrhythmic effect, or (3) a proarrhythmic effect, Holter monitoring is required. To make this judgment a baseline recording is needed. Most often such a recording can be made for 24 hours, and treatment started immediately after removing the monitor. However, in some dogs the VT may be too dangerous to permit a full 24-hour baseline recording. For these dogs the longest baseline recording that is believed to be safe is performed, and the animal started on medication after this time. Because it is not known if medication will improve the VT, it can be argued that the baseline is as important as the treatment. This is true because some dogs do experience proarrhythmic effects from drugs used as antiarrhythmic medication. Therefore the standard of care for the treatment of VA is:

1. Obtain baseline 24-hour Holter monitor recording in the environment where the medication will be administered (home).
2. Treat with the selected medication and dosage.
3. Recheck 24-hour Holter recording in 7 to 10 days after questioning to ensure compliance.
4. Evaluate for change in frequency or severity of the VA and determine if treatment is successful or not.

If the VA counts and severity are not altered, the dosage of medication is usually increased if possible, and the Holter recording repeated 7 to 10 days later. If the VAs are not suppressed, an alternative or additional medication can be given. When combinations of antiarrhythmic drugs are used (e.g., sotalol plus mexiletine), caution and close monitoring are absolutely needed to avoid side effects.

In some dogs an oral medication that is effective cannot be found. In humans the use of the implantable cardioverter-defibrillator has supplanted many of the drugs in the treatment of VAs. This may be an option for some dogs afflicted with potentially fatal VT such as the boxer or the German shepherd; however, the use of these devices is limited to centers that have the ability to monitor and program them to ensure proper functioning.

In the evaluation of the Holter recordings an important consideration is the definition of an adequate antiarrhythmic response or a proarrhythmic response. Limited studies have been done in dogs, but it is likely that a marked reduction of VA by 75% and VT by 90% is required in an individual dog to state that a true antiarrhythmic effect has occurred. If such strict criteria are not met, the reduction actually may be the result of day-to-day variability. It is also possible for an antiarrhythmic effect to occur only with VT and not with single VAs. We have noted in the treatment of boxers that sotalol in some dogs suppresses the frequency of VT by more than 90%, but the number of single VAs does not change. Moreover, borrowing from human medicine, to say that a proarrhythmic effect has developed, a 10-fold increase in VT must be documented. Consequently, to try and monitor the drug effect on VA without Holter monitoring is ineffective.

Because most dogs undergoing treatment for VT have underlying structural or functional disease, monitoring requires attention to these aspects of cardiac function. Thus additional monitoring with thoracic radiography and echocardiography is common. Moreover, examination of blood chemistry profiles in such cases is warranted. It should be stressed that, if an owner reports any problems that are new after a medication has been started, it is wisest to blame the drug first. Assessment of side effects is important, and only if a critical approach is taken can serious problems be avoided. The most common problems reported are vague and relate to overall well-being in addition to complaints of anorexia. Other complaints reported include twitching, change in behavior, and disorders related to hepatotoxicity.

CHAPTER 163

Feline Cardiac Arrhythmias

ETIENNE CÔTÉ, *Prince Edward Island, Canada*

NEIL K. HARPSTER, *Boston, Massachusetts*

Normal cardiac impulse formation arises within specialized fibers of the sinoatrial (SA) node and when necessary in specialized atrial tissues and parts of the atrioventricular (AV) conduction pathways and His-Purkinje system. Alterations in normal cardiac rhythm, or cardiac arrhythmias, arise as a result of either focal or diffuse primary disorders affecting the heart. Examples include inflammation, infarction, ischemia, infiltration, degeneration, and primary cardiomyopathies. Arrhythmias also may develop secondary to generalized systemic disorders such as hypoxemia, systemic hypertension, hyperkalemia, sympathetic stimulation, hyperthyroidism, or severe anemia.

ETIOLOGY

The mechanisms responsible for cardiac arrhythmias are categorized generally as disorders of impulse formation, disorders of impulse conduction, or combinations of the two (Côté and Ettinger, 2005). Some arrhythmias may be initiated by one mechanism and perpetuated by another. The initiating factor in many arrhythmias involves a reduced resting cell membrane potential.

Because of the small size of domestic cats and their correspondingly small hearts, cats appear to be at reduced risk for the development of cardiac arrhythmias compared to other closely monitored species (dogs, horses, humans). Advanced heart disease may be present before the occurrence or recognition of arrhythmias, given the lifestyle of

family pet cats that seem to pace themselves so well and minimize their clinical signs.

Primary cardiac disorders associated with cardiac arrhythmias include congenital cardiac disorders and acquired disorders. Cardiac arrhythmias are uncommon in cats with congenital cardiovascular disease (Harpster, 1987 and 1992) but have been recognized in severe conditions associated with marked cardiomegaly or heart failure. Exceptions include the tachyarrhythmias associated with ventricular preexcitation and conduction abnormalities associated with septal defects.

Most acquired cardiac disorders of cats, if sufficiently severe, can be associated with arrhythmias. The cardiomyopathies (hypertrophic, intermediate/ restrictive/ unclassified, and dilated) have commonly been associated with bradyarrhythmias and tachyarrhythmias. Generally tachyarrhythmias predominate when congestive heart failure (CHF) or aortic thromboembolism (ATE) occurs, whereas bradyarrhythmias are more common in association with episodes of syncope or in patients in cardiogenic or terminal shock (Fox and Harpster, 1999).

In cats hyperthyroidism is a well-documented cause of cardiac arrhythmias, including sinus tachycardia, supraventricular and ventricular premature complexes, or tachycardias; conduction abnormalities are also common, including first-degree AV block, left anterior fascicular block, and both right and left bundle branch block, although cause and effect are not proven and similar arrhythmias are seen in old cats.

Heartworm disease has been associated with cardiac arrhythmias in cats, mainly when cats are showing overt clinical signs caused by heartworm infection or following adulticidal therapy (Tilley, 1992; Harpster 1987; Harpster, 1992; Fox and Harpster, 1999). Ventricular premature complexes (VPCs) and other arrhythmias may occur.

Systemic diseases of noncardiac origin may be associated with cardiac arrhythmias, likely through altering circulatory blood volume, the presence of deleterious circulating levels of toxic substances or electrolytes, or high sympathetic tone (Tilley, 1992; Harpster 1992; Harpster 1987; Fox and Harpster, 1999). Specific recognized causes include reperfusion injury, acute shocklike states, thoracic or abdominal trauma, metabolic acidosis, disorders of the brain and spinal cord, hyperkalemia, hypokalemia, and hypomagnesemia.

Evaluation of the Arrhythmic Cat

Electrocardiographic recording in the cat with suspected cardiovascular disease or arrhythmia should include, minimally, leads I, II, III, aVR, aVL, and aVF, and a precordial lead (e.g., V4, also called CV6LU). Additional precordial leads may provide a clearer diagnosis, especially when motion artifact of the limbs is present or P waves are small.

Events reported by the owner, including episodic ataxia, collapse, vocalizing, syncope, or seizures, may lead the clinician to suspect intermittent arrhythmias. Clients and veterinarians can readily confuse syncope and seizures in cats. If arrhythmias are absent initially, diagnostic studies to differentiate between neurologic and cardiovascular events should be pursued. Ideally this should begin with a 24-hour period of observation in a veterinary critical care facility with continuous electrocardiographic monitoring. Beyond this, when primary neurologic episodes have tentatively been ruled out and/or the cost of additional hospitalization is prohibitive, additional options include Holter or event monitoring.

Electrocardiography is the diagnostic test of choice for cardiac arrhythmias in cats, but an ECG alone does not provide adequate information for identifying causes, selecting treatment, and establishing a prognosis that address the whole patient. Therefore every cat with an arrhythmia requires a complete clinical evaluation.

History

In cats, cardiac arrhythmias occur most commonly in conjunction with primary heart disease. Compared to dogs, cats less commonly have cardiac arrhythmias caused solely by extracardiac disturbances. Therefore the clinical history reflects manifestations of cats with heart disease in general, ranging from none (the arrhythmia is an incidental finding) to evidence of CHF or ATE.

Cardiac arrhythmias usually are found incidentally in cats; overt manifestations caused by arrhythmias are rare. For example, cardiac arrhythmias occur in 20% to 40% of cats with ATE, but syncope is rarely described in these cats (Laste and Harpster, 1995; Smith et al., 2003). Similarly, in 50 cats with atrial fibrillation the arrhythmia was found incidentally in 11 (22%), but no cat had a chief complaint convincingly attributable to arrhythmia

(Côté et al., 2004a). Therefore the presenting complaint of a cat with an arrhythmia generally appears to occur as a result of the underlying heart disorder and not the arrhythmia itself.

Physical Examination

The physical examination of a cat with an arrhythmia involves more than auscultating the heart and palpating the pulse. The examination begins with an initial, hands-off *observation* of respiratory effort, posture (e.g., flaccid neck ventroflexion as is seen with severe hypokalemia), mentation (e.g., extreme anxiety and concurrent dyspnea commonly noted with CHF or ATE), gait (e.g., deficits may be seen with ATE), and body condition (e.g., emaciation with hyperthyroidism). Assessment of *mucous membrane color* may reveal cyanosis with hypoxemia or pallor with hypoperfusion or anemia. Gentle *palpation of the ventral neck* evaluates the thyroid glands in older cats. *Palpation of the cardiac impulse and peripheral pulse* are essential; relevant abnormalities can include bilateral increase in the apex beat (cardiac enlargement), displacement of the apex beat to the right (right ventricular enlargement, apex shift, or mass lesion), a palpable thrill, or presence of a heartbeat without a corresponding pulse (intermittence suggests premature beats, but complete pulselessness suggests embolism or severe hypotension). *Cardiac auscultation*, including auscultation over the sternum in addition to both hemithoraces, reveals the heart rate; presence of a regular rhythm or arrhythmia; and presence or absence of murmurs, a gallop sound, or other abnormal sounds. Sudden pauses may indicate postextrasystolic pauses, AV block, or sinus pause or arrest. *Palpation* of the abdomen and limbs and assessment of the extremities for normal color and warmth are also essential.

Laboratory Testing

Routine laboratory tests consisting of a complete blood count (CBC), serum biochemistry profile, and urinalysis (and serum thyroxine level in cats >6 years old) are indicated as part of the minimum database in every cat with a cardiac arrhythmia. Broadly speaking, these tests seek to identify one of two classes of abnormalities: disturbances that are a clue toward finding the underlying cause of the arrhythmia (e.g., CBC evidence of leukemia in a cat with cardiac lymphoma) or disturbances that may directly alter the rhythm of the heart (e.g., hyperkalemia, hypokalemia, anemia, metabolic acidosis).

Serologic testing for feline leukemia virus (FeLV) and feline immunodeficiency virus (FIV) is warranted as part of the evaluation of any ill cat. However, FeLV- and FIV-associated disease is rarely associated with arrhythmias. Cardiac lymphoma, in association with FeLV or FIV, has been reported sporadically in a small number of cats.

Diagnostic Imaging

Thoracic radiographs are indicated in all cats with a cardiac arrhythmia. Possible abnormalities include findings consistent with heart disease (cardiomegaly; infiltrates

suggesting pulmonary edema; pleural effusion) or systemic illness (pleural effusion, infiltrates suggesting pneumonia or metastases). The goals of obtaining radiographs are to guide treatment (e.g., thoracocentesis if large-volume pleural effusion; diuretics if pulmonary edema), to identify further points for testing (e.g., metastases warranting a tumor search), and to contribute to determining the prognosis.

Echocardiography remains the diagnostic test of choice for identifying structural heart disease in cats. An echocardiogram is indicated in every cat with a cardiac arrhythmia, even when there are no historical signs or other physical signs to suggest a cardiac disorder. This is because certain “silent” forms of heart disease such as restrictive/unclassified cardiomyopathy may produce no historical or physical signs other than the arrhythmia (Côté et al., 2004a).

Blood Pressure Measurement

Measurement of the arterial blood pressure, preferably by Doppler flow methodology, is indicated in all cats with cardiac arrhythmias. The normal range for systolic arterial pressure in a calm, unsedated cat is 100 to 170 mm Hg in the clinical setting.

Systemic hypertension may trigger cardiac arrhythmias via ventricular hypertrophy or through a comorbid condition such as hyperthyroidism. An arrhythmic hypertensive patient needs to be evaluated for causes (hyperthyroidism, chronic renal failure, white coat effect) and effects (retinopathy, neurologic deficits) of hypertension.

It is worth noting that arrhythmias other than inappropriate sinus tachycardia do not cause systemic hypertension; the more severe a bradycardia or a tachycardia becomes, the more likely it is to produce hypotension. Systemic hypotension in cats with arrhythmias may be caused by a generalized disorder that predisposes to arrhythmia such as hypovolemia or cardiogenic shock. Alternatively, systemic hypotension may be caused by the arrhythmia itself, since both very high or very low heart rates can compromise cardiac output. An arrhythmic, hypotensive cat also needs to be evaluated for causes of hypotension other than the arrhythmia such as blood loss and profound dehydration.

Arterial blood pressure may be difficult to measure in a patient that is persistently arrhythmic. The solution is to wait until the arrhythmia has subsided (even briefly) to measure the blood pressure during sinus rhythm or at least during a period when the rhythm is fairly regular and at a rate that approaches normal. The gold standard is direct measurement using an intraarterial catheter and pressure transducer, which may be appropriate in critically ill cats but requires special skills and equipment.

CARDIAC ARRHYTHMIAS: DIAGNOSIS AND MANAGEMENT

Very little information has been published regarding the prevalence of cardiac arrhythmias in pet cats. Table 163-1 lists the results of an original retrospective study of abnormal ECGs from 170 consecutive cats with cardiovascular disease admitted to the cardiology service of the Angell Animal Medical Center over a 20-month period.

Table 163-1

ECG Findings in 170 Consecutive Feline Patients With Recorded Abnormalities over a 20-Month Period

	Number	Percent
I. Cardiac bradyarrhythmias and conduction abnormalities		
A. AV conduction abnormalities (total)	(20)	(11.8)
1. First-degree AV block	10	5.9
2. Second-degree AV block	1	0.6
3. Third-degree AV block	10	5.9
B. IV conduction abnormalities	(82)	(48.2)
1. Left anterior fascicular block	32	18.8
2. Right bundle branch block	15	8.8
3. Left bundle branch block	5	2.9
4. Other IV conduction abnormalities	30	17.5
II. Cardiac tachyarrhythmias		
A. Supraventricular (SV)	(41)	(24.1)
1. Supraventricular premature complexes (SPCs)	26	15.3
2. Paroxysmal SV tachycardia	11	5.9
3. Atrial fibrillation	5	2.9
B. Ventricular (V)		
1. Ventricular premature complexes (VPCs)	(57)	(33.5)
a. Right ventricular origin ^a	19	11.2
b. Left ventricular origin ^b	29	17.1
c. Multiform ^c	9	5.3
2. Ventricular bigeminal rhythm	6	3.5
3. Ventricular triplets ^d	4	2.4
4. Paroxysmal ventricular tachycardia	3	1.8
5. Coupled ventricular premature complexes	7	4.1
C. Both SV and V arrhythmias ^e	17	10.0
III. Other ECG abnormalities		
A. Left ventricular hypertrophy pattern ^f	38	22.4
B. Gigantic P waves ^g	8	4.7

AV, Atrioventricular; ECG, electrocardiographic; IV, intraventricular.

^aThe characteristic feature or a right ventricle–origin premature complex is a dominant R wave deflection in leads II and CV6LU.

^bThe characteristic feature of left ventricle–origin premature complexes is a dominant S wave deflection in leads II and CV6LU.

^cECG recordings with multiform ventricular premature complexes have separate/individual premature complexes with the right ventricle–origin and the left ventricle–origin premature complex characteristics.

^dA ventricular triplet consists of three consecutive ventricular premature complexes beats in a row.

^eThe 17 cats with both supraventricular and ventricular arrhythmias had an average left atrial:aortic ratio of 2.18 with a range of 1.21 to 3.32.

^fLeft ventricular hypertrophy pattern is characterized by the presence of R waves of 1 mV or greater in both leads II and CV6LU.

^gGigantic P waves are characterized by P waves in lead II that are 0.4 mV or greater in amplitude.

Normal sinus rhythm is the normal heart rhythm in resting cats. The heart rate is 110 to 180 beats/min. On ECG (Fig. 163-1) a P wave is followed by a QRS complex and a T wave; the R-R interval is constant, and the P waves; QRS complexes, and T waves maintain the same shape or morphology. In the home environment healthy cats on resting examination have a heart rate

Fig. 163-1 Normal sinus rhythm in a cat. Heart rate = 160 beats/min, 50 mm/sec, 1 cm/mV.

of 118 ± 11 beats/min when examined by veterinary student-owners with a stethoscope (Hamlin, 1989) or a mean rate of 157 ± 3.7 beats/min on 24-hour Holter recordings (Ware, 1999).

Bradycardias (Bradycardias)

Sinus bradycardia has the same ECG features as normal sinus rhythm, but the heart rate is less than 110 beats/min. Because of the same ambient factors that cause sinus tachycardia, sinus bradycardia in cats in an examination room setting is extremely unusual. At home sinus bradycardia (rates as low as 68 beats/min) occurs routinely in the cat (Ware, 1999). However, in the clinical setting sinus rhythm at a rate less than 140 beats/min is unusual (Côté et al., 2004b) and can be considered to be a relative sinus bradycardia that warrants further diagnostic evaluation. Drugs (β -blockers) and anesthetics can create sinus bradycardia. Systemic disorders, including brain disease, hypothermia, and diseases causing high vagal tone should be a focus of diagnostic evaluation. The triad of shock, hypotension, and hypothermia is also commonly associated with sinus bradycardia in cats.

AV block (heart block) refers to hampered transmission of electrical activity through the AV conduction system. It may occur in one of three degrees of severity: all impulses successfully but slowly cross the AV system (first degree), some impulses cross but not others (second degree), or complete AV block (third degree). *First-degree AV block* is exclusively an ECG finding. It produces a PR interval greater than 0.09 seconds but no clinical or physical signs. Causes include digoxin toxicity, high vagal tone states, and structural heart disease.

Second-degree AV block, an intermittent failure of impulses to cross the AV node, produces P waves not followed by QRS complexes on ECG. Second-degree AV block traditionally is divided into two subtypes. With Mobitz type I or “Wenckebach” conduction through the AV node gradually slows over a few beats until ultimately block occurs. In Mobitz type II, conduction through the AV system has a fixed PR interval until, without forewarning, a P wave is blocked (Fig. 163-2). The occurrence of clinical signs depends on the number of blocked impulses and presence of escape activity. The greater the number of blocked impulses, the slower the resultant ventricular rate; therefore the more likely are overt signs such as syncope, especially if escape complexes do not develop. In the cat second-degree AV block is usually Mobitz type II and is most commonly associated with cardiomyopathy, conduction system degeneration, or the administration of such α -2 agonist drugs as medetomidine. Individual variation and digoxin toxicity are less common causes. Treatment is justified when AV block is causing overt signs such as hypotension or syncope. Except when caused by drugs, medications such as vagolytic drugs (e.g., propanteline) or β -agonists are not consistently beneficial for treating AV block, and treatment generally involves the implantation of a pacemaker.

With *third-degree AV block*, impulses are formed normally in the SA node, travel normally through the atria, and are all blocked in the AV conduction system. The ECG appearance is one of AV dissociation (Fig. 163-3). The atrial rate is faster than the ventricular (escape) rate. Ventricular activity is from an escape rhythm: QRS complexes that are different in shape from normal QRS complexes occur at a regular, slow (60 to 140/minute) rate. Notably the

Fig. 163-2 Second-degree atrioventricular (AV) block in a cat—intermittent, Mobitz type II AV block. In this tracing the P waves are positive, and the normal sinus QRS complexes are negative. The fourth P wave is blocked (*first arrowhead*), without a preceding lengthening of the PR interval. The fifth P wave is also blocked (*second arrowhead*). Superimposed on the fifth P wave is a QRS complex that appears after a period of ventricular inactivity and is of a different shape than the normal QRS complexes; it is a ventricular escape beat (*arrow*). The next P wave is conducted normally, but the seventh and eighth are not, and the same type of AV block is again apparent. The eighth P wave is followed by another ventricular escape. 25 mm/sec, 1 cm = 1 mV.

Fig. 163-3 Incidentally discovered third-degree arteriovenous block in a 17-year-old cat with hypertrophic cardiomyopathy. The fourth P wave is not seen because the second ventricular escape beat is superimposed over it. Artifactual undulation of the baseline is present and not clinically significant. Heart rate = 80 beats/min, 25 mm/sec, 1 cm = 1 mV.

escape rhythm is faster in cats than in dogs. Occasionally cats are observed with periods of profound ventricular asystole, which then recovers.

Third-degree AV block occurs almost exclusively in older cats (≥ 11 years old) and is caused by or associated with cardiomyopathies (Kaneshige et al., 2006), infiltrative heart disease (e.g., lymphoma), other structural heart diseases, or hyperthyroidism. It may occur idiopathically, probably from degeneration. It is generally permanent, although occasionally a cat may revert to second-degree AV block or to sinus rhythm (Kellum and Stepien, 2006). Chief complaints for cats with third-degree AV block include exertional dyspnea, respiratory distress, collapse, or none. Like second-degree AV block, the repercussions of third-degree AV block on a cat depend on stability of the escape activity and the ventricular rate. With low heart rates or erratic escapes, cats are more likely to show overt signs requiring treatment (pacemaker implantation). Such treatment is considered if the ventricular escape rate is constantly slow (< 100 beats/min) and/or if the cat shows intermittent signs directly associated with bradycardia or asystole on ECG, Holter, or event monitor. The diagnosis of third-degree AV block in the cat does not in itself warrant treatment because, when the ventricular rate is adequate, there may be no signs, and the prognosis may not be affected. Some cats develop cardiomegaly and mild CHF that may be managed medically.

Atrial standstill (atrial paralysis, silent atria) involves complete absence of detectable atrial electrical activity. On ECG a regular R-R interval, generally with QRS complexes of the same shape and size, and no P waves are seen (Fig. 163-4). The two most common causes in cats are hyperkalemia and atrial myopathy (especially severe atrial stretching caused by primary heart disease). Two steps are essential when atrial standstill is suspected in a cat:

Fig. 163-4 Atrial standstill in a cat with hyperkalemia caused by urethral obstruction. Serum K^+ = 7.1 mEq/L. No P waves are seen, nor were they present in any other ECG lead. The heart rate is 205 beats/min. 25 mm/sec, 1 cm = 1 mV.

the evaluation of other ECG leads to seek out P waves (that may be isoelectric in one lead) and measurement of the serum potassium concentration to rule out hyperkalemia-induced atrial standstill. If serum potassium is less than 7 mEq/dl, an echocardiogram is warranted to evaluate the structure of the heart. Unlike dogs and humans, cats with severe hyperkalemia and atrial standstill do not necessarily have bradycardia, and heart rates as high as 240 beats/min are routinely present in cats despite severe hyperkalemia. Cats with hyperkalemia-induced atrial standstill require treatment of the underlying disorder as well as hyperkalemia. Although the optimal treatment is controversial, we use calcium gluconate (10% solution; 0.5 to 1.5 ml/kg infused slowly intravenously [IV] and discontinued if the heart rate decreases or the QRS complexes widen). Other possible treatments include sodium bicarbonate (1 to 2 mEq/kg very slow IV bolus) or the combination of regular insulin 0.25 to 0.5 units/kg IV with 2 g/kg of dextrose (= 4 ml/kg of 50% dextrose, preferably diluted before administration). Cats with normokalemia and atrial standstill require treatment specific to the form of underlying heart disease. Some cats in cardiogenic shock with apparent atrial standstill redevelop P waves with successful therapy.

Tachyarrhythmias (Tachycardias)

Tachyarrhythmias indicate a rapid heartbeat. In cats the suspicion of a pathologic tachyarrhythmia should be considered when the heart rate consistently approaches or exceeds 240 beats/min or when irregularities in the cardiac rhythm are noted. *Sinus tachycardia* (Fig. 163-5) has the same ECG features as normal sinus rhythm, but the heart rate is higher than 180 beats/min. The PR interval is normal (0.04 to 0.09 seconds) and is inversely proportional to heart rate. The significance of sinus tachycardia in the cat is highly variable. Most cats brought into a veterinary environment have sinus tachycardia even when healthy. The median heart rate on auscultation of 89 healthy cats in hospital was 180 beats/min (range: 140 to 260) (Côté et al., 2004b). The heart rate of 27 healthy cats undergoing an in-hospital ECG was 182 ± 20 beats/min (Hamlin, 1989). Therefore sinus tachycardia is considered normal for a cat in a veterinary setting. However, sinus tachycardia also may occur in pathologic states. Anemia, hypotension, hyperthyroidism, sepsis, fever, pain, and other systemic disorders cause sinus tachycardia. Therefore the finding of sinus tachycardia must be placed in context. Sinus tachycardia does

Fig. 163-5 Sinus tachycardia in a 15-year-old domestic shorthair cat with compensated hypertrophic cardiomyopathy and endocarditis of the aortic valve. The heart rate is 220 beats/min. The T wave is essentially isoelectric and poorly seen in this lead. A small amount of motion artifact is seen throughout the baseline. 25 mm/sec, 1 cm = 1 mV.

not cause clinical signs and rather is the result, not the cause, of physiologic or medical disturbances. It usually must not be suppressed because doing so would compromise the call for increased cardiac output or the need for reflex tachycardia. Some clinicians treat cats with severe sinus tachycardia ($\approx 300/\text{min}$) associated with hyperthyroidism with atenolol; however, this therapy typically is unnecessary once the thyrotoxicosis is controlled.

Supraventricular tachyarrhythmias are tachycardias in which the arrhythmia arises within the atria or the AV junction. Included are supraventricular (atrial) premature complexes, supraventricular (atrial, AV junctional) tachycardias, atrial flutter, and atrial fibrillation. Tachycardias mediated by an accessory pathway that bypasses the AV node such as Wolff-Parkinson-White syndrome can be considered supraventricular as well.

Supraventricular tachyarrhythmias usually develop secondary to enlargement, inflammation, or infarction of atrial myocardium. Common causes include AV valve regurgitation, diastolic dysfunction (hypertrophic or restrictive cardiomyopathies), atrial fibrosis or infarction, or less commonly in the cat primary valvular degeneration or infection (endocarditis). Other recognized causes include congenital cardiac disorders (i.e., atrial and ventricular septal defects, patent ductus arteriosus) and hyperthyroidism.

In most cases supraventricular tachyarrhythmias have the characteristic ECG features of normally conducted QRS-T complexes, except for the absence of a preceding P wave (Fig. 163-6). Atrial tachycardia is often an exception in that normal or abnormally conducted P waves are usually recorded. On occasion supraventricular tachyarrhythmias resemble ventricular arrhythmias when intraventricular conduction is abnormal

(i.e., aberrant) in the former. Differentiation of an aberrantly conducted supraventricular tachycardia (SVT) from ventricular tachycardia (VT) might be accomplished during the recording of an ECG by the application of a vagal maneuver: for 10 to 15 seconds gentle pressure is applied to the region just dorsal and cranial to the larynx (unilateral carotid sinus massage), or moderate pressure is applied on the eyeballs bilaterally over closed eyelids, or the nasal planum is depressed gently for 10 to 15 seconds. If this fails, diltiazem (see following paragraphs) may create AV block, an alteration that should block abnormal P waves or flutter waves, terminate a reentrant SVT, or have no effect on a VT.

Supraventricular premature complexes (SPCs, including atrial premature complexes) are characterized by the premature occurrence of a normal QRS complex. Generally in cats there is no visible P wave for an SPC (Fig. 163-7), and only on occasion does a clear, premature P wave precede the premature QRS complex. Common associations with SPCs include structural heart disease, but on occasion they occur secondary to high stress or systemic disorders. Specific treatment of SPCs is not indicated unless they are frequent (i.e., accelerating the ventricular rate to $>200/\text{minute}$) or repetitive in nature. Under these circumstances they should be managed as for the patient with SVT (see next paragraphs).

SVT implies an accelerated cardiac rhythm that requires rapid activation above the ventricles (i.e., atria or AV tissues). The QRS complexes usually have the normal, expected configuration, but P waves generally are absent or buried in the prior QRS ST-T waves, and the heart rate commonly exceeds 240/min (see Fig. 163-6). As mentioned previously, on rare occasions the QRS complexes in SVT may resemble VT because of aberrant ventricular conduction, which is best demonstrated via a vagal maneuver.

Fig. 163-6 Supraventricular atrial tachycardia. QRS complexes are narrow and positive in this lead II tracing, suggesting a supraventricular source for the initiating impulse. They are also tall, suggesting left ventricular enlargement. The rhythm is regular and rapid (heart rate = 290/min). Very large, abnormal P waves are seen clearly and repeatedly at the end of the QRS complex and are conducted with first-degree atrioventricular block. Ectopic P waves are often concealed within the preceding T wave or QRS complex. 25 mm/sec, 1 cm = 1 mV.

Fig. 163-7 Atrial premature complexes. The regularity of this sinus tachycardia (heart rate = 280/min) is interrupted by two supra-ventricular premature complexes, which are the fifth and seventeenth heartbeats (arrows). The QRS complexes and T waves of these premature beats are the same as those of the sinus beats. 25 mm/sec, 1 cm = 1 mV.

Management of the cat with SVT usually requires combined management of both the arrhythmia and the heart failure that generally accompanies it. Therefore furosemide, oxygen therapy, and continuous ECG monitoring often are the cornerstones of initial care, frequently without antiarrhythmic drugs. In a cat with sustained SVT, specific management of the arrhythmia commonly is chosen in light of the underlying heart disease. For example, in addition to oxygen and diuretic therapies, sustained SVT in a cat with hypertrophic cardiomyopathy may be treated with either a calcium channel blocker or a β -blocker (see dosage under section on Ventricular Tachycardia later in the chapter), whereas SVT in a cat with dilated cardiomyopathy may be treated with digoxin with or without β - or calcium channel blockade.

Atrial fibrillation (AF) is characterized by a complete disorganization of atrial activity without effective atrial contraction. Characteristics on ECG are an isoelectric or irregularly undulating baseline, QRS complexes of a consistent though slightly varying shape, and an irregular ventricular rhythm that is generally rapid (mean: 223 ± 36 beats/min) (Fig. 163-8). In most cats the initiating factor appears to be advanced structural heart disease associated with marked left atrial enlargement. For example, the mean left atrial:aortic ratio in one study was 2.55 ± 0.80 (Côté, 2004a). Chief complaints commonly may be perceived as relating to heart disease (e.g., dyspnea, acute paralysis) but in 22% of cats AF is found incidentally. It occurs more often in males (Côté et al., 2004a).

In AF, ventricular rate control can be achieved by adequate control of CHF and use of medications that decrease conduction through the AV node. After control of fluid congestion, drugs chosen for ventricular rate control in AF are selected based in some cases on the underlying structural heart disorder (see previous paragraph on SVT). In general, diltiazem is most effective for blocking

AV nodal conduction and can be combined with digoxin or a β -blocker. The negative inotropic effects of diltiazem and atenolol must be appreciated. The prognosis with AF in cats is fair in our experience, with median survival of 165 days and 33% of cats with AF living 1 year or more.

Ventricular Tachyarrhythmias

A ventricular tachyarrhythmia occurs as a result of the early and unnecessary electrical activation of the ventricles. The resulting QRS-T complex precedes or obliterates the sinus P wave, and the QRS conformation is different from that of the normally conducted QRS complex (Figs. 163-9 and 163-10). In most instances the QRS complex in a ventricular tachyarrhythmia is producing a dominant R wave in leads II and V4 when the impulse originates in the right ventricle and a dominant Q wave, S wave, or QS complex when it arises in the left ventricle. In cats that also have an intraventricular conduction abnormality such as bundle branch block, the site of origin of the ventricular arrhythmia may be more difficult to accurately define. Four or more consecutive VPCs are a *ventricular run* or VT. Ventricular tachyarrhythmias are the second most common class of ECG abnormalities in cats (see Table 163-1).

In most cats with ventricular tachyarrhythmias, the arrhythmia is a marker of underlying myocardial disease. The presence of a ventricular tachyarrhythmia strongly identifies the need for a thorough patient workup as discussed initially in this chapter and ideally either a Holter monitor study or a 24- to 48-hour period of ECG monitoring in a veterinary critical care facility. Only by taking this approach can the significance of the arrhythmia be fully established and accurate decisions pertaining to therapeutic interventions made. Although the majority of cats with sporadic or infrequent ventricular tachyarrhythmias do not require antiarrhythmic therapy, frequent repetitive

Fig. 163-8 Atrial fibrillation. The QRS complexes are supraventricular in appearance (narrow, upright in lead II), but the R-R interval is completely irregular, there are no visible P waves, and there is a finely undulating baseline. Heart rate = 260/minute, 25 mm/sec, 1 cm = 1 mV.

Fig. 163-9 Ventricular premature complexes (VPCs). The first QRS complex is a normal sinus complex, as evidenced by its preceding P wave and normal shape. The same is true for the other odd-numbered complexes on this tracing. The remaining complexes are wider, taller, and clearly different in shape compared to normal. They also occur prematurely. This alternating pattern between sinus beat and VPCs is termed *ventricular bigeminy*. The P waves also are tall, suggesting atrial enlargement. 25 mm/sec, 1 cm = 1 mV.

Fig. 163-10 Ventricular premature complexes (VPCs) and ventricular tachycardia (VT). The first is a normal sinus heartbeat, followed by two VPCs of varying morphology; the fourth beat appears to be a supraventricular premature beat occurring directly after the second VPC. The next beat is a normal sinus beat followed by five VPCs in a row—a run or "paroxysm" of VT that terminates spontaneously. During sinus rhythm there is substantial ST segment elevation (0.2 mV), suggesting myocardial hypoxia. 25 mm/sec, 1 cm = 1 mV.

VPCs or runs of VT that tend to promote cardiovascular instability (lethargy, low blood pressure, weakness or syncope, CHF) demand recognition and therapy.

Initial management must include identification and correction of precipitating factors such as hypokalemia, anemia, thyrotoxicosis, and hypoxemia. When aggressive (rapid, polymorphic) ventricular tachyarrhythmias are identified or when aggressive diuretic and oxygen therapy do not reduce the frequency of such arrhythmias in a cat with CHF, antiarrhythmic drug therapy should be introduced. Optimal therapy of ventricular arrhythmias in cats is poorly understood. Care must be used when giving negative inotropes such as β -blockers to cats with hypotension or uncontrolled CHF; with rare exceptions, these types of drugs are not initiated until such unstable conditions have improved or resolved.

A reasonable starting point is to evaluate the therapeutic response to an intravenous β -blocker (e.g., propranolol, 0.25 to 0.50 mg/cat IV slowly over 2 to 3 minutes; or esmolol, 0.05 to 0.5 mg/kg IV bolus over 1 to 2 minutes or administered as a constant rate infusion [CRI] at 50 to 200 mcg/kg/min). Alternatives include an intravenous lidocaine bolus (0.25 to 1.0 mg/kg over a 3- to 5-minute period; CAUTION: cats anecdotally are reported to be sensitive to the adverse effects of lidocaine) or procainamide (10 to 20 mcg/kg/min IV CRI); if this proves effective oral procainamide at 1/4 of a 250-mg tablet BID to TID is introduced as the IV infusion is gradually tapered down over 24 to 48 hours.

Following the acute control of life-threatening ventricular tachyarrhythmias or in the patient with less aggressive but

worrisome ventricular tachyarrhythmias, oral antiarrhythmic agents should be considered. Options include procainamide (62.5 mg/cat PO BID to TID), propranolol (2.5 to 5 mg/cat PO BID to TID), or atenolol (6.25 to 12.5 mg/cat PO SID to BID). Others have used sotalol (2 mg/kg orally [PO] q12h). Beyond the initial patient evaluation and hospitalization, follow-up patient evaluation studies need to be pursued. These can range from periodic outpatient examinations with ECG recordings to the Holter monitor studies previously mentioned or even day-patient monitoring in a critical care facility when these facilities are available.

CHAPTER 164

Cardioversion

JANICE M. BRIGHT, *Fort Collins, Colorado*
JULIE MARTIN, *Englewood, Colorado*

External electrical cardioversion refers to transthoracic delivery of a direct current (DC) shock for restoration of sinus rhythm in patients with ventricular or supraventricular tachyarrhythmias. The shock is synchronized to the R wave of the QRS complex to avoid induction of ventricular fibrillation. Synchronized energy delivery distinguishes cardioversion from defibrillation, which is unsynchronized. Until recently electrical cardioversion and defibrillation were done in humans and dogs using equipment that delivered a monophasic energy waveform (i.e., a high energy electrical shock sent a current across the chest in a single direction). However, newer cardioversion/defibrillation devices are available that deliver biphasic energy waveforms. These biphasic cardioverter/defibrillators use a lower-energy, self-reversing waveform that is safer and more effective than traditional monophasic shocks.

Biphasic electrical cardioversion has potential advantages over pharmacologic cardioversion in that a precisely regulated “dose” of electrical energy can restore sinus rhythm immediately and safely. Also, the distinction between supraventricular and ventricular tachycardia is less crucial with electrical cardioversion than with medical management. Finally, time-consuming titration of drugs with potential side effects is not an issue with DC cardioversion. However, a disadvantage of electrical cardioversion for emergency management of tachyarrhythmias is that the equipment and expertise may not be readily available. Moreover, when electrical cardioversion is done as an elective procedure, general anesthesia is required.

Electrical cardioversion appears to be most successful for termination of tachycardias resulting from impulse reentry such as atrial fibrillation, atrial flutter, atrioventricular node reentry, atrioventricular reciprocating tachycardias involving an accessory conduction pathway, and most forms of ventricular tachycardia. The electrical shock is believed to terminate the tachycardia by simultaneously depolarizing all excitable myocardium and possibly by prolonging refractoriness; in other words, the shock interrupts reentrant circuits and establishes electrical homogeneity, thereby terminating reentry.

INDICATIONS AND CONTRAINDICATIONS FOR DIRECT CURRENT CARDIOVERSION

Any tachycardia producing hypotension or congestive heart failure that does not respond promptly to medical management is a candidate for electrical cardioversion. The exception to this general rule would be a digitalis-induced tachyarrhythmia.

DC cardioversion done as an elective procedure is useful for restoring sinus rhythm in patients with sustained atrial fibrillation or atrial flutter. By improving hemodynamics (reducing ventricular filling pressures, augmenting cardiac output, decreasing ventricular rate, and providing atrioventricular synchrony), rhythm control is potentially beneficial for dogs with congestive heart failure and secondary atrial fibrillation (Dernellis, Stenfanadis, Toutouzas, 2000; Sisson, Brown, Riepe, 1995). Furthermore, restoring sinus rhythm circumvents the need for pharmacologic control of heart rate using

drugs that often have a negative inotropic effect such as β -blockers and diltiazem (McNamara et al., 2003). In the absence of underlying heart disease, restoration of sinus rhythm in dogs with atrial fibrillation diminishes the risk of secondary thromboembolism and prevents tachycardia-induced cardiomyopathy. In athletic dogs there may also be an improvement in exercise tolerance. In dogs with atrial flutter, pharmacologic control of the ventricular rate is frequently difficult, and DC cardioversion is often our initial treatment of choice.

Electrical cardioversion is contraindicated in patients with cardiac glycoside toxicity, and there is an increased risk associated with electrical cardioversion in animals with sinus node dysfunction that do not have a pacemaker. Finally, DC cardioversion is contraindicated in patients with intraatrial thrombus because organized atrial contraction may dislodge the thrombus.

CARDIOVERSION PROCEDURE
